The only question presented in this case now was decided in *Electric Gas Lighting Company* v. *Tillotson* on the same patent. It is whether the fifth claim of the reissue is supported by the original, and has been reargued and reconsidered. The patent is for an electric gas-lighting apparatus. The foundation for this fifth claim is sought for in the original first claim. That was for a circuit-breaker located at the burner and operated automatically, substantially as described. This is for the combination of a wire through which a current of electricity is passed, actuating mechanism for letting on the gas, an electro-magnet connected with the wire, an armature operated by the magnet, mechanism, actuated by the armature, breaking the circuit at the burner and producing sparks for lighting the gas, the whole operating automatically. The specification is the same in both the original and reissue. The inventor might have claimed upon it everything which he has claimed; but that is not sufficient. *Manufacturing Company* v. *Ladd*, 102 U. S., 408. The reissue is between eight and nine years later than the original, and could not lawfully cover what was not either claimed in some manner in the original or included within what was so claimed. (*Mahn* v. *Harwood*, 112 U. S., 360.) This claim of the reissue is for machinery breaking an electric circuit at the burner and producing sparks there to light the gas. It may or may not include machinery for turning on the gas. The claim in the original was not for any machinery, but the circuit-breaker. It was for the circuit-breaker operated; but that did not include the machinery to operate it. If it included the operation, that is a different thing from the means by which the operation is performed. *James* v. *Campbell*, 104 U. S., 356; *Powder Company* v. *Powder Works*, 98 U. S., 136. So, whether this claim in the reissue includes the machinery for turning on the gas or not, it is for a part of the invention not claimed in the original (*Turner & Seymour Company* v. *Dover Stamping Company*, 111 U. S., 319); and as the claim in the original was not for any combination of parts, the combination of this claim of the reissue cannot be said to be the same combination further restricted by additional elements, and is not included in what was claimed in the original. The patent for the circuit-breaker as located and operating, and machinery for turning on the gas, without the machinery for operating the circuit-breaker, appears to have been satisfactory at the time when the patent was taken out, and for so long a time afterward, that it could not be made to cover the machinery for operating the circuit-breaker. The conclusion reached is the same as before.

Let there be a decree dismissing the bill of complaint.

THE HENRY MEMORIAL TABLET.

One of the features of the coming commencement at Princeton college will be the unveiling of the Henry memorial tablet, which is now being completed by a New York architect. President McCosh has decided to insert the tablet in the east wall of the Marquand chapel, north of the chancel, facing the nave. Invitations have been extended by the donors of this memorial gift to all the leading scientists in America to be present at the unveiling ceremonies on Tuesday, June 16. The tablet will be presented to the college by Mr. Dickerson, a prominent member of the New York Bar, with an appropriate address. It will be received for the college, with addresses, by president James Mc Cosh, Prof. Cyrus F. Brackett Henry, Professor of Physics, Prof. Charles A. Young, and Prof. J. Stillwell Schenck, the latter of whom assisted Prof. Henry in his laboratory work at Princeton college. Another address will be made by some leading scientist who has not as yet been selected. This memorial is the first that has ever been erected to any of Princeton's illustrious instructors. Prof. Joseph Henry performed most of his renowned experiments in electricity during his connection with this college. He used for his laboratory the cellar of old Philosophical Hall—now removed, and which formerly stood on the present site of the college library. In the museum of the physical laboratory is the largest electro-magnet Prof. Henry constructed, together with other of his machines, now having a great historic value.

THE CLAIMS OF THE EDISON ELECTRIC LIGHT CO.

The Edison Electric Light Co. of this city issued the following circular, May 23d, in regard to their legal claims to certain patents:

First—That the patents of Mr. Thomas A. Edison, now the property of this company, fully cover the exclusive manufacture, sale, and use of any and all practical incandescent electric lamps.

Second—That the Edison company, having begun suits at law for the enforcement of its rights under these patents, will not relax in their vigorous prosecution.

Third—That the Edison company is prepared to fully guarantee and protect all its customers, and to prosecute and punish, to the full extent of the law, all makers, sellers, or users of incandescent lamps not duly authorized by it.

The late attempt to establish for the Sawyer-Man patent, just issued, a fundamental character is made upon wholly superficial ground, and will not bear the test of close analytical examination. Edison's patent of January, 1880, applied for at the time of his great discovery, covers broadly all the elements of that discovery, and is therefore, fundamental and controlling. The Sawyer-Man patent, constructed in the light of the knowledge of 1885, but having for its foundation unsuccessful laboratory experiments, only covers certain details of manufacture of carbons, as, for instance, paper and the specific genus of material to which it belongs, and is therefore secondary and subordinate. The claim that the Sawyer-Man patent is fundamental, simply because the narrow and valueless claim to the use of paper has been illegally and without notice to Edison broadened to a claim for all fibrous material, carries its own condemnation. If anything more is necessary to demolish it, it may be stated that Edison, Swan, and others have already used materials absolutely non fibrous, in preference to a material the claim for which is now held to control the construction of a practical lamp. The public have nothing to fear from the use of the lamp as supplied by the original inventor and discoverer, while they render themselves liable for damages by the use of his fundamental patent for a "filament of carbon" if unauthorized by the Edison company.

THE EDISON ELECTRIC LIGHT CO., by EDWARD H. JOHNSON, Vice-President.

ANNUAL MEETING OF THE RHODE ISLAND TELEPHONE AND ELECTRIC CO.

The annual meeting of the Rhode Island Telephone and Electric Co. was held in Providence on the 6th ult. The report of the secretary and manager J. W. Duxbury, showed that subcompanies had been formed in Boston, New Bedford, Fall River, Taunton, Brockton, Worcester, Springfield, Pittsfield, Lowell, Lawrence, Lynn, Newburyport, Salem and Attleboro in Massachussets; and in Providence, Woonsocket, Pawtucket and Westerly, in Rhode Island; and that negotiations were pending in New Hampshire and Connecticut. The treasurer's report, showed a balance in excess of capital and liabilities of $35,000. They have paid during the year two dividends of four per cent. each, amounting to $8,000. The old board of directors was re-elected and also the following officers: President, Henry Howard; treasurer, Chas. T. Howard; secretary and general manager, J. W. Duxbury; assistant-general manager, F. H. Gardiner.

INCANDESCENT LIGHTING IN NEW YORK AND BROOKLYN.

During the past month an isolated plant of 350 incandescent lamps has been started by the United States company at the Hamilton club, Brooklyn. They are distributed in all parts of the building, gas being entirely dispensed with. An installation of the same extent is nearly completed in the Brooklyn *Eagle* building. The new ferryboats Colorado and Wyoming with Weston plants are now running.

The plant at the New York Post-office, comprising 1400 lamps, has been running satisfactorily for a fortnight, and has been examined and approved by Mr. Thomson the chief government inspector It comprises seven 200-light dynamos driven by one Porter-Allen and one Buckeye engine. This is the fifth post-office which has been fitted up by the United States company. The arc-lamps at the Coleman House are being superseded by the large Weston incandescents. They will be supplied with a current from the Stanton street station, two and one-half miles distant.

OWNERSHIP OF THE BALTIMORE AND OHIO RAILROAD TELEGRAPH CO.

A short time ago a bill was filed against the Baltimore and Ohio company by a stockholder in the road alleging that the railroad had no authority under its charter to maintain a telegraph organization, that the Baltimore and Ohio Telegraph Co. was detrimental to the stockholders of the railroad, and that the officers of the company were unduly interested in the telegraph. It concluded by praying for an injunction restraining the company from further maintenance of the telegraph company. This

Digitized by Google

action bore some marks of having originated from a Western Union source. The answer of the railroad company, which was somewhat delayed, has been at last filed, and makes denial of all the allegations of the complaint. It declares that the company has authority to maintain the telegraph company, and that so far from being detrimental to the road, the telegraph company, which is being rapidly extended throughout the country, is fast becoming the source of a large revenue to the road; it is owned in toto by the Baltimore and Ohio Railroad Co., and no officer of the road is interested privately in it.

THE NEW YORK ELECTRICAL SOCIETY.

The meeting of May 13th took the form of a tour of inspection by the members of the society through the very complete electric lighting station of the United States Illuminating Co., at 34 Stanton street in this city. There can be no more effective impression produced of the growth of this new industry, than by visiting an important station of this character, where notwithstanding the immense aggregation of machinery the excellent arrangement of the engines and dynamos permits a close examination of every detail. The visitors were thoroughly pleased with their investigations which were not only instructive but exceedingly interesting.

The Electrical Society has removed to its new quarters at 234 Broadway, opposite the post-office. The library and reading-room are accessible to members every week-day, and on the second and fourth Wednesday evenings of each month the regular meetings will be held at the same place.

CONFERENCE OF TELEPHONE LICENSEES.

The American Bell Telephone Co. has issued invitations to all companies licensed under its patents to send delegates to a conference at Boston June 8th. The session will continue for five days, during which the delegates will be the guests of the parent company. It is supposed that a reduction in rentals to sub-companies will be considered, and possibly adopted, in view of the antagonistic legislation which is cropping out in various parts of the country.

ANNUAL MEETING OF THE NEW ENGLAND TELEPHONE CO.

On May 15th, the new board of directors of the New England Telephone Co. met and completed their organization by the election of an executive committee as follows: Theo. N. Vail, W. H. Forbes, Thomas Sherwin and Chas. J. Glidden, the latter in place of W. A. Ingham resigned. Three of the four gentlemen are officers of the American Bell Telephone Co., which company accordingly retains the executive management in its own hands.

CORRECTION.

Through a misunderstanding of the facts a foot-note to the article on Atmospheric Electricity in the May issue of this journal, stated that the author had been awarded the Jones prize at the New York Electrical Society. This was not the case, the official decision not having been made as yet.

THE ELECTRIC LIGHT ASSOCIATION.

The chairman of the executive committee of the National Electric Light Association announces a meeting of the committee to be held at Union Square Hotel in New York city, on June 9th at 10 o'clock a. m.

ASSOCIATION OF RAILWAY TELEGRAPH SUPERINTENDENTS.

The third annual meeting of Railway Telegraph Superintendents will be held at the Weddell House, Cleveland, Ohio, at 10 a. m., June 17th.

ELECTRIC LIGHT AND POWER.

Domestic.

The New Britain Schuyler Electric Light Co. has been incorporated in Connecticut, with a capital of $25,000.

The Mobile Electric Light Co., Mobile, Ala., is putting in a Thomson-Houston plant.

A Pittsburg corporation, known as the Duquesne Electric Co., was chartered at Wheeling, W. Va., April 28. The capital stock is $600,000, of which sum $2,500 has been subscribed.

The Jefferson Bain Electric Light and Power Co., of Chicago, has been incorporated, with a capital stock of $25,000.

The Commissioner of Patents has denied a motion for a rehearing in the patent interference proceedings of Siemens against Edison against Field. The matter at issue was a patent for the application of electricity as a motive power to railway cars by means of the rails, and the decision of the Commissioner sustains the findings of the Examiners in awarding priority of invention to S. D. Field, of New York.

The Edison Electric Illuminating Co., of New Brunswick, N. J., has been incorporated to construct and maintain works for the manufacture and supply of electricity for lighting, heating and power. Capital stock, $50,000.

The Pine Bluff Electric Light and Power Co, capital stock $25,000, has been organized in Pine Bluff, Ark., to build electric-light works.

The American Electric and Illuminating Co. is starting an electric-light station at Poughkeepsie. It will put in two Armington & Sims engines, a steel tubular boiler, which will be set with the Jarvis furnace to burn screenings and slack coal, also a National feed-water heater.

Messrs. Wm. B. Hayes, John E. Wyman and L. T. Griffin, of Detroit, have incorporated into the Van Depoele Construction Co., for the purpose of supplying the cities and towns of Michigan with electricity for light and motive power.

The Franklin Electric Light and Power Co., of New York city, has been incorporated for general purposes, chiefly manufacturing.

The Brush-Swan Electric Light Co., of Central New York, has been incorporated, with a capital of $150,000. It will enter at once into the business of both arc and incandescent lighting, having already bid for the street lighting of Utica, outside the "naphtha" district, for $19,500 per year.

The United States company has been awarded the contract for lighting the State Insane Asylum at Fulton, Mo., with 450 Weston 16-candle-power lamps.

The New Lots Electric Lighting Co., of New Lots, N. Y., has been incorporated to manufacture electrical appaaratus. Capital stock, $15,000.

Foreign.

The electric light is to be used on all the trains running through the St. Gothard tunnel.

It is reported that, at the forthcoming Antwerp exhibition, the commission will endeavor to establish units of work and of cost for each type of dynamo, and for each purpose to which it may be applied.

It is proposed to run electric tram-cars from Victoria bridge, London, to Battersea, provided permission can be obtained from the Board of Trade.

Messrs. Wheatley Kirk, Price and Goulty have instructions to sell by auction the plant and stock of the "Pilsen, Joel and General Electric Lighting Co." and of the "Electric Lighting Supply and Fitting Co."

MANUFACTURING AND TRADE NOTES.

Domestic.

The firm of A. K. Eaton & Co. has been formed for manufacturing and dealing in electrical, philosophical and optical instruments, at 65 Henry street, Brooklyn.

The electrical supply business of Wm. R. Pope & Co., of Baltimore, Md., has been assigned to James B. Guyton.

Paul Revere founded the copper works in Canton in 1800, which were incorporated as the Revere Copper Co., in 1828. During all these years copper was never so low in price as now, still the company manages to run regular hours, though not with their full force. Some of the great-grandsons of Paul Revere are now in the concern, and part of the house in which he lived is still in existence.

Foreign.

A firm in Glasgow, Scotland, is now manufacturing ribbon wire for electric purposes. It is nearly rectangular in section, and thus can be wound into a smaller space than round wire, while its greater flexibility renders it far more easy to manipulate. It is marked with the same numbers as the corresponding sizes of round wire, and is delivered on wooden bobbins.

MISCELLANEOUS.

Domestic.

An automatic electric steering apparatus constructed for the government steamer "Despatch" was tested on May 6th at Brooklyn.

A press despatch from Oil City, Pa., says that a column of gas from a large gas well in that vicinity was recently struck by lightning and ignited. It is still burning and will be difficult to extinguish.

Digitized by Google

Foreign.

The English Admiralty has ordered that all the guns of every vessel leaving Chatham shall be supplied with arrangements for being discharged by electricity, and that several of the larger ships will be provided with the electric light.

The Triboulet system of photographing all the country as seen from a captive balloon is said to have succeeded well. A very small balloon carries up to the necessary height the photographic apparatus, the panoramic object-glass of which is provided with a valve which can be opened through an electric current managed by the operator, who remains on the ground. The impressions obtained are useful for military purposes.

The new clock dials on the tower of the general Post-office at Melbourne, Australia, will be made of cast-iron having hemispherical recesses so placed as to mark the hours, instead of the usual numerals. These cups will be nickle-plated inside so as to reflect the sunlight, forming bright points during the day-time. After dark each will be illuminated by an incandescent lamp, and on each of the hands will be placed a close row of smaller lamps. By this arrangement it is believed that it will be possible to read the time at a great distance.

THE TELEGRAPH.

Domestic.

On May 25 Judge Phelps, at Baltimore, signed a decree ordering the sale at auction of all the property of the Bankers and Merchants' Telegraph Co., upon the bill of complaint of Francis P. Stevens. The property is to be sold June 18.

By an unfortunate blunder of the train despatcher at Ashley, Pa., a collision between a locomotive and a freight train occurred near Wilkesbarre, Pa., on the Lehigh and Susquehanna division, May 16, by which two lives were lost.

Foreign.

China, which only six years since had but six miles of telegraph lines, has now completed a system by which Canton, the capital of Southern China, is brought into direct communication with the metropolis of the north.

Extensive preparations are being made in the British post-office department to meet the increased traffic expected from the adoption of the sixpenny rate for telegrams. It is expected that in the first year there will be an increase in the total number of telegrams of 30 per cent. Half a million pounds have already been expended for new poles, wires, instruments, etc. Over 20,000 miles of additional wires have been laid, and 1,200 extra operators, and over 1,000 new messengers, will be engaged.

THE TELEPHONE.

Frederick W. Watkins, president and chief owner of the Mutual Telephone Co., at No. 1 Broadway, New York, has made an assignment, without preference, to Bernard Metzger. The company was formed to exploit an acoustic telephone.

A bill limiting telephone rentals to $3 per month for single instruments, and $2.50 where more than one is used, has been passed by the House of Representatives in Illinois.

The Freeman telephone is now announced from Washington as the instrument which is to make trouble for the American Bell company, unless it is bought up at once.

INVENTORS' RECORD.

Prepared expressly for The Electrician and Electrical Engineer *by* Pope & Edgecomb, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From April 7th, to May 12th, 1885 (inclusive).

Alarms and Signals:—*Burglar Alarm*, A. W. Hall, 315,139, 315,140, April 7; F. G. Lyon, 316,376, April 21; J. H. Hill & J. E. Babcock, 316,621, April 28. *Annunciator*, J. E. McDuff and J. F. Doherty, 315,313, April 7. *Electro-Mechanical Gong-Striker*, L. H. McCullough, 316,476, April 28. *Multiple Signal-box for Fire and Police Telegraphs*, same, 316,477. *Push-button*, T. C. Frenyear, 317,450, May 5. *Annunciator and Fire Telegraph*, C. K. Pevey, 317,569, May 12. *Call-box*, F. B. Wood, 317,912.

Clocks:—*Movement*, J. E. Carey, 316,112, April 21. *Pendulum Clock*, F. and O. Haenichen, 316,360.

Commutators:—*Switch or Circuit Controller*, E. Weston, 316,096, April 21. *Switch or Circuit-Breaker*, same, 316,097.

Conductors, Insulators, Supports and Systems:—*Underground Conduit for Conductors*, G. H. Benjamin, 315,225, April 7; A. E. Lytle, 315,954, April 14; W. Walter, 316,700, April 28. *Electric Coupling*, T. T. Smith, 315,673, April 14. *Lightning Conductor*, F. R. Upton, 315,679. *System for Transmitting Power*, W. L. Stevens, 316,076, April 21; E. Weston, 316,090. *Aerial Conduit for Wires*, D. B. Macquarrie, 315,526, April 14. *Fire-telegraph System*, L. H. McCullough, 316,474, April 28. *Non-interfering Fire-telegraph System and Apparatus*, same, 316,475. *Insulators*, H. Kellogg, 315,633, April 14; H. Prenzel, 315,660, J. Locke and W. Bowker, 316,469, April 28; 316,812, W. H. Wright, 317,479, May 5. *Support for Underground Lines*, S. J. Fague, 317,326, May 5. *Vulcanization of Rubber Coverings for Conductors*, J. J. C. and M. Smith, 317,587, May 12. *System of Distribution*, W. S. Andrews, 317,700. *Conductor for Wire Fencing*, C. Williamson, 317,908.

Dynamo Machines and Motors:—*Motor*, C. G. Perkins, 315,161, April 7; F. J. Sprague, 315,179, 315,180. *Motor and Generator*, same, 315,181, 315,182. *Electro-Dynamic Motor*, same, 315,183. *Motor*, E. Weston, 316,091, 316,092, 316,093, April 21. *Governor for*, W. M. Thomas, 316,500, April 28. *Reciprocating Engine*, C. J. Van Depoele, 317,249, May 5. *Dynamo*, C. F. Heinrichs, 317,779, May 12. *Armature for*, W. F. Buckley, 315,903, April 14. *Regulator for*, E. Weston, 316,089, April 21.

Galvanic Batteries:—A. Haid, 315,937, 315,938, April 14; E. Bazin, 316,436, April 28. *Rotary Battery*, same, 316,437. *Battery Fluid*, I. L. Roberts, 317,206, May 5.

Ignition:—*Fire-arm*, F. E. Kinsman, 317,545, May 12. *Gas lighter*, E. H. Wright, 316,428, 316,429, April 21; J. A. Norton, 315,057, April 7. *Gas-lighting Apparatus*, same, 315,055, 315,056. *Cartridge for Electric Fire Arms*, 317,409, May 5.

Lamps and Appurtenances:—*Arc-Lamps*, W. F. Buckley, 315,473, April 14; M. N. Lynn, 315,524, F. M. Sparrow, 315,564, April 14; G. A. Tabourin, 315,571, L. Colburn, 316,240, April 21; C. F. Heinrichs, 317,777, 317,778, M. G. Farmer, 316,765, W. W. King, 316,791. *Incandescent Lamps*, E. Weston, 316,094, C. H. F. Muller, 317,171, May 5; T. A. Edison, 317,631, 317,632, 317,633, May 12; W. E. Sawyer and A. Man, 317,676. *Filament for*, W. Stanley, Jr., 316,302, April 21. *Holder for Incandescent Lamp*, P. H. Brangs, 316,003, April 21; E. Weston, 316,088. *Bracket*, same, 316,095. *Electric Light Apparatus*, T. T. Smith, 315,674, April 14. *Safety-box for Circuits*, W. L. Stevens, 316,077, April 21. *Electric Lighting System*, E. Weston, 316,707, 316,708, 316,709, April 28, *Automatic Cut-out for Incandescent Lamps*, W. M. Thomas, 316,501, 316,502. *Apparatus for Carbonizing Incandescents*, O. A. Moses, 316,993, May 5. *Electric Lighting System and Switch*, W. S. Andrews, 317,610, May 12. *Apparatus for Making Curved Carbons*, C. F. Heinrichs, 317,776. *Wiring Interiors for Electric Lights*, L. Stieringer and J. H. Vail, 317,879.

Metallurgy:—*Magnetic Separator*, C. F. Hilder and E. Scott, 315,028, April 7. *Apparatus for Refining Copper by Electrolysis*, M. G. Farmer, 315,265. *Apparatus for Obtaining Aluminum*, M. G. Farmer, 315,266. *Apparatus for the Separation of Gold from its Ores*, E. P. Thompson, 317,245, May 5. *Apparatus for the Electro-deposition of Gold from its Chlorides*, same, 317,246.

Miscellaneous:—*Means for Adjusting Armature Springs*, J. F. Gilliland, 315,017, April 7. *Means for Re-setting Armature Drops*, C. W. Holtzer, 315,035. *Passenger Recorder*, A. Torrey and D. J. Casey, 315,855. *Apparatus for Transmitting to Moving Objects*, L. Goldberg and A. L. Fyfe, 316,139, April 21. *Induction Machine*, P. Haerry, 316,143. *Driving Apparatus for Centrifugal Machine*, A. Watt, 316,316, 316,317, April 21. *Coil for Induction and other Electrical Apparatus*, L. Gaulard and J. D. Gibbs, 316,354. *Elevator*, S. S. Wheeler, 10,585, Re-issue. *Induction Coil*, T. J. Perrin, 316,817, April 28. *Weighing and Recording Device*, E. H. Amet, 317,432, May 5. *Glass Cutting Machine*, P. Lange and E. Lindiner, 317,805, May 12. *Compressed Air and Gas Locomotive*, D. S. Troy, 317,891. *Gas Engine*, same, 317,892. *Velocipede*, same, 317,893.

Railways and Appliances:—*Railway*, B. Bidwell, 315,113, April 7; F. J. Sprague, 317,235, May 5. *Circuit for Switch Signals*, A. W. Hall, 315,498, April 14. *Rail Connection*, H. D. Winton, 315,586. *Alarm for Trains*, S. C. Pullman, 315,662. *Signaling Apparatus*, W. Hadden, 315,772. *Railroad Signal*, J. Hinds and L. L. Stimpson. *Conduit for Railway*, E. Samuel, 315,841, T. C. Clarke, 317,302, May 5. *Mechanism for Automatically Operating Throttle and Brake Valve of Locomotives*, T. Potter, 316,171, April 21. *Alarm and Signal*, H. C. Roome, 316,183, April 21. *Signaling Apparatus*, C. D. Tisdale, 316,201. *Track Instrument*, H. D. Winton, 317,910, May 12. *Signal*, same, 317,911.

Storage Batteries:—E. T. Reichert, 315,339, 315,340, April 7; W. A. Shaw, 316,407, 316,408, 316,409, April 21. *Primary and Secondary Battery*, G. Fournier, 316,533, April 28. *Accumulator*, J. J. Barrier, F. Tourveille, and J. E. Legay, 317,487, May 12.

Telegraphs:—*Autographic*, S. P. Denison, 315,391, 315,392, April 7. *Induction Apparatus for Telegraphy*, J. C Ludwig, 315,425. *Current Reversing Key*, same, 315,426. *Polarized Relay*, same, 315,427. *Generation of Induced Currents*, same, 315,428. *Harmonic Printing Telegraph*, G. A. Cardwell, 315,121, 315,122. *Relay*, F. Stitzel and C. Weinedel, 315,568, April 14. *Sounder*, J. F. Gilliland, 315,763. *Transmitting Apparatus*, P. B. Delany, 316,125, April 21. *Receiving Apparatus for Synchronous Telegraphy*, same, 316,126. *Synchronous Telegraphy for Fac simile Transmission*, same, 316,754, April 28. *Printing Telegraph*, A. B. Smith, 316,494, H. Van Hoevenbergh, 316,677, 316,678, 316,679. *Electro-Magnet for*, same, 316,676. *Type-wheel for*, same, 316,682, 316,683, 316,684. *Platen-shifting Device for*, same, 316,685, 316,697. *Pneumatic Winding Apparatus for*, same, 316,688. *Automatic Governor for Transmitter*, same, 316,687. *Method of Unisoning Instruments having two Type-wheels*, same, 316,690. *Unison Device for Printing Telegraphs*, same, 316,855, 316,691, 316,696. *Inking-roller for*, same, 316,692. *Page-printing Telegraph*, same, 316,680, 316,681. *Chemical Printing Telegraph*, same, 316,689. *Chemical or Fac-simile*, same, 316,693. *Method of Printing Telegraphically*, same, 316,694. *Winding Device for Printing Telegraphs*, same, 316,695. *Receiver for*, same, 316,698. *Relay*, G. W. Gardinier, 316,956, May 5.

Telephone Systems and Apparatus:—*Signaling Apparatus and Circuit*, F. Herzog, 315,027, April 7. *Angle Hanger for Acoustic Telephone Line*, H. Seligman, 315,078. *Switch-board*, T. J. Perrin, 315,331. *Exchange Circuit*, same, 315,334. *Apparatus for the Transmission of Messages by Electricity*, G. T. Woods, 315,368. *Automatic Call for Latent Signal Transmitters*, F. B. NEW YORK, JULY, 1885.

THE EDISON ELECTRIC LIGHT PATENTS.

IN commenting in our last issue upon the claim which has been put forth by the Edison Electric Light Co., that the patents of Mr. Edison are such as to "fully cover the exclusive manufacture, sale and use of any and all practical incandescent electric lamps," we expressed the opinion that these pretensions would prove to be untenable, and that the manufacture and sale of incandescent lamps could not be summarily monopolized in this manner. In order that our readers may have some idea of the grounds upon which our opinion was based, we have prepared, and publish in another column an analysis of the principal claims of the three incandescent lamp patents which are mainly depended upon to establish the exclusive claims of Mr. Edison, together with the text of the patents, and a summary of certain provisions of the patent law and decisions of the courts, which are likely to have an important bearing upon these particular patents. We have given also the principal facts in relation to the prior discoveries and inventions of others, and other information, which, it is thought, will enable the reader to understand the probable nature of the defenses which will be set up in the course of the pending litigation.

No one can be more ready than ourselves to admit the fact that the present advanced state of practical and commercial incandescent electric lighting owes a great deal, directly and indirectly to Mr. Edison. Nor can anyone have a higher appreciation of the ingenuity, industry and exhaustless perseverance which has been manifested by Mr. Edison in the development of his electric lighting system, and especially of the peculiar ability which he has shown in inspiring capitalists with that implicit faith in his inventive abilities, in default of which the present development of domestic electric lighting would doubtless have been postponed for years, simply from the lack of adequate financial backing. It would be superfluous for us to comment upon the perfection with which the apparatus in its mechanical and scientific details has been worked out. It is in operation in every part of the world and speaks for itself. But while awarding a proper share of the credit of the general result to Mr. Edison and his associates, it is but right and just that the work which has been contributed by others should meet with at least a fair share of recognition. Other inventors were in the field long before Mr. Edison, and their contributions towards the ultimate result, were certainly as important if not more important, than his own. In fact Edison's work could not have been carried to a successful result, had he not freely availed himself of the discoveries and inventions of Gramme, Alteneck and Weston, in dynamo-electric machines, of Farmer in the regulation and distribution of electricity, and of Geissler, Sprengel, Crookes and Gimingham, in the conduction of electricity through high vacua, and the improvement of the mercurial air-pump. Other inventors founding their labors upon the researches of these same predecessors have developed systems of incandescent lighting, certainly not inferior to that of Edison in efficiency, economy, and general adaptibility to general purposes.

It is just at this point that we take issue with the policy which has been pursued by Mr. Edison and the Edison company. In his patents Mr. Edison has asserted, and his company now proposes to undertake to enforce, his exclusive right to make, sell, and use incandescent lamps. As we have already said, we do not believe that this claim can be sustained. We entertain no doubt that if Mr. Edison had been contented to confine his claims strictly to the improvements which were actually made by him, instead of endeavoring to include not only what he had done himself, but everything which had been done by others as well, the situation might have been very different from what it is at present. But in his eagerness to monopolize the entire art of incandescent electric lighting, he is apparently in danger of finding himself in the situation of the dog in the fable, who lost the bone he had in his mouth by trying to assert his claim to the other bone which he saw reflected in the water. What ultimately became of the bone ; whether it was captured by another dog or not, the fable does not state, nor can we forecast the result of the present proceedings with much greater certainty.

THE IMPORTANCE OF SCIENTIFIC TRAINING.

ALTHOUGH there is abundant evidence at the present time of the existence of a widespread interest in electrical investigation, either as a study, a recreation, or a means of livelihood, there are frequent manifestations of a desire on the part of persons in whom the commercial instinct has been abnormally developed, to secure the skill, the knowledge and the experience which is possessed by the expert, without that essential preliminary training, which is popularly, and correctly, supposed to be obtainable only through many years of study and experiment, accompanied with a large proportion of hard work. In every branch of handicraft there will be found a large proportion of workers who do not believe in "the books," and who neglect no opportunity to publicly declare their views. They are men

Digitized by Google

who prefer in every case to derive wisdom from their own experience, rather than profit by the researches of others. This is to a certain extent perfectly right and proper; yet life is too short at the best for any one of us to learn every detail of a profession by personal experience—to prove by the hard test of actual failure, and consequent loss of time and money, that a certain method of procedure is radically wrong, when that information might have been just as satisfactorily obtained by studying the investigations of others in a similar field.

In the early stages of electrical industry the science was in a comparatively crude state. Electricity was looked upon as a mysterious and uncertain agency, for the simple reason that its laws were comparatively unknown. Although a few scientists had investigated it as an interesting branch of physics, those who were called upon to deal with it commercially were not only almost entirely ignorant of its peculiarities and its possibilities, but were unable to solve its problems, simply for the reason that the lapse of time was necessary in order that experience might develop its various characteristics.

Electrical science stands to-day upon an entirely different footing. The literature of the subject is rapidly—perhaps too rapidly—multiplying in every branch. Not only are its fundamental laws thoroughly understood, but its exact capabilities and economies, down to the very acme of refinement, may be demonstrated by well-established methods, perfectly accessible to all who have sufficient faith in the value of scientific research to familiarize themselves with them.

There are not a few who are considered intelligent men, who believe that theory and practice are separated by an impassable gulf, and who look upon the literary work, even of a thoroughly practical man, as the mere vaporings of an enthusiast.

Scientific study and training are deemed an indispensable foundation for the career of the successful physician or civil engineer. It is certainly no less essential for the electrical engineer, and the time is rapidly and certainly approaching when the financial success of all enterprises depending upon the most economical transmission of electrical energy will demand the supervision of men who not only possess practical experience, but who are thoroughly versed in the progress of the art, both at home and abroad.

We have reason to believe that there exists in many quarters a disposition to ridicule the treatment of practical electrical work from a scientific standpoint, and to assert that the attainment of the highest degree of electrical knowledge does not necessarily involve a resort to mathematics or text-books. The early workers in the telegraphic field groped in the darkness, because of their excusable ignorance of the subtle agency with which they had suddenly been confronted. The telephone service developed a multitude of new investigators, many of whom ostentatiously ignored the long-established rules of conductivity, resistance and insulation. There were those who stood high in the service who held that the smaller the conductor the better the result, because of the diminished inductive effects, while the matter of insulation was of no importance whatever. Even the sleet-storms, which the old-time telegraphers had learned by experience to dread, were considered a mere bugaboo. A few years of practical experience have changed all this, and we find to-day that the electrical laws which were recognized as governing telegraphic conditions are admitted to be equally applicable to the telephone. The same may be said of the more powerful dynamic currents with which we are now becoming familiar. To be sure the field is extending, and the thorough electrician must soon extend his researches beyond the confines of his own territory into the domain of mechanical and civil and marine engineering. Those who would attain that complete knowledge of their profession which will surely lead to success, must seek to acquire the necessary stock of information to aid in equipping them for the task. While many practical workers are to-day standing aghast at the apparently incomprehensible array of equations, formulæ and tables, which, because they do not understand, they consider to be useless, the well-trained young graduate from the polytechnic school is entering the field, with a mental equipment which enables him, after a short practical experience, to secure those higher positions which must necessarily be filled by electrical engineers who are masters of their profession. The machinery which is now being brought into use, and the electric currents which are employed in connection with it, are matters not to be trifled with. Ignorance cannot be tolerated, for the consequent damage to property and life, as well as the adoption of inefficient and expensive methods, will surely absorb the profits, which are already too small to permit of any waste. The inexorable laws of commercial competition are certain, in the end, to crush out the ignorant and the incompetent, and to leave the trained and skilful expert master of the field.

ELECTRIC LIGHTING SCHEMES.

Among the many devices resorted to in modern times for obtaining money under false pretences, we know of none more reprehensible than that of forming corporations, the sole object of which is in reality the advancement of the pecuniary interests of their promoters and manipulators. Electrical enterprises, and especially electric lighting, have offered an uncommonly fine field for such enterprises, and now that the larger cities have been thoroughly worked up, we observe that very special attention is being devoted to the rural districts.

In order to entice the unwary investor a schedule is prepared, in which the fullest details are apparently given respecting the cost of plant, the running expenses, and, most important of all, the net profit, which, in certain cases within our knowledge, has been placed at over 50 per cent.

It is difficult to imagine upon what basis such a statement of profit can be figured out.

We are quite well aware that whatever we may say in reference to these fallacious statements will not be very likely to reach the future victims of these delusive enterprises; but we regard it as anything but conducive to the permanent interests of electrical industries that such schemes should be continually cropping out in various forms, and under different aliases, that each promoter should endeavor to befog the mind of the public with vociferous statements that his concern is the original Jacobs, and all others spurious imitations, unworthy of

Digitized by Google

public confidence. Practically, both the arc and incandescent systems of electric lighting, in a general sense, have been freely open to competition. There are, of course, numerous improvements and economical devices, owned and controlled by different interests; and in the earlier periods of electric light development there were no doubt plenty of opportunities for obtaining large profits, by reason of the ignorance of purchasers as to the state of the art. All this is now changed, and we find that in most installations of any importance competitors are invited to submit proposals for contracts to be awarded to the lowest bidder. It is not our purpose to assert that this state of affairs is the most beneficial one, either to the vender or the public, but simply to emphasize the fact that there is no legitimate foundation for the expectation that large profits can be realized by the introduction of electric lighting systems, especially in small towns. It is, no doubt, true that in many cases exclusive franchises may be obtained in very favorable localities, which may lead up to a fairly profitable business, returning dividends possibly of eight or ten per cent. If there are any local companies which have done better than this, and at the same time laid aside a reasonable margin for the renewal of plant, or for placing their wires underground, we should be pleased to learn the details of a system which has thus proved itself in every respect a satisfactory business investment. We see no reason why a statement of the exact facts should be detrimental to the healthy development of the electric lighting industry. If it is desirable to obtain the good will of the public, claims of exorbitant profits will not be likely to prove advantageous, while if it is true that immense gains may be realized, we think that the privilege of obtaining them should be reserved for the benefit of that select circle of friends who are entitled to admission on the ground floor.

IMPORTANT DUPLEX TELEGRAPH LITIGATION.

The duplex telegraph, which was introduced on the lines of the Franklin Telegraph Co. in 1868, and on those of the Western Union in 1872, was never commercially successful until after the addition to the original apparatus of a condenser for neutralizing the electro-static effects which are manifested upon long lines. A patent for this improvement was granted to Joseph B. Stearns in 1872, and was purchased by the Western Union Telegraph Company. It is the ownership of this patent more than anything else which has enabled the Western Union company to maintain for more than a dozen years, a virtual monopoly of duplex and quadruplex telegraphy.

During the past year the Baltimore and Ohio company is understood to have made extensive use of the condenser in connection with its duplex and quadruplex circuits. The Western Union company, on June 22d, made application for an injunction against the Baltimore and Ohio Telegraph Co., its agents and employés, alleging an infringement of the Stearns patent. The motion was to have been heard on June 26th, but has been postponed for three weeks.

This will probably prove to be one of the most important patent suits which has ever occupied the attention of the courts in this country. It is no exaggeration to say that the Stearns invention has been worth many millions of dollars to the Western Union company, and the result of the proceedings will be awaited with the greatest interest in telegraph circles. It is not known what line of defense will be adopted by the Baltimore and Ohio company, but inasmuch as the action has been commenced on a reissue which was taken out nine years after the date of the original patent, it is not difficult to conjecture that in view of many recent decisions of the Supreme Court, one of the principal defenses will be that the reissued patent is invalid. Assuming the patent to be valid there would seem to be little doubt of the fact of infringement, provided the Baltimore and Ohio company makes use of the condenser in connection with an artificial line, as it may be presumed that it does.

Messrs. Buckingham, Dickerson and Duncan appear as attorneys for the Western Union, and Messrs. Lowrey and Bacon for the Baltimore and Ohio.

THE TELEPHONE CONFERENCE.

The recent gathering of representative telephone men in Boston took the form of a private business conference, at which views were freely exchanged as to the proper policy to be pursued in order to obtain the best financial results, and at the same time appease a certain tangible, though not altogether well-defined feeling of enmity against the home company, which has gradually become so considerable as to be worthy of attention.

In offering explanations to the subscribers for the exaction of the prevailing rates, which vary all the way from $20 to $150 per annum, according to the circumstances, the royalty paid for the use of the instruments has been one of the most convenient pretexts, because it has served to relieve the local managers from the imputation of oppressing their friends and neighbors. This was a very natural thing to do, and as the officers of the American Bell Telephone Co. were securely intrenched behind the convenient shield known as a board of directors, no particular harm was done, until antagonistic statutes began to be enacted by the various state legislatures. The result of all this agitation has been a reduction of one-half in the royalty—from $12 to $6 per year—also the abolition of the rental of central office telephones. This change may perhaps not be universal, as our information on the subject is somewhat meagre; but at all events, certain concessions were made, which under the seductive influence of boundless hospitality, appear to have been generally acceptable to the guests of the alleged "monopoly." Whether the rural telephone subscriber is to be permitted to share in the benefits of the new schedule, will doubtless be a question for future consideration. When he inquires into the matter he will without difficulty ascertain that the visiting statesmen had a good time; but if he presses for further information, the conversation may assume substantially the form of that in the beautiful lines of Southey, so familiar to every schoolboy:

> "And everybody praised the duke
> Who this great fight did win.
> 'But what good came of it at last?'
> Quoth little Peterkin.
> 'Why, that I cannot tell,' said he,
> 'But it was a famous victory.'"

ARTICLES.

AN ANALYSIS OF SOME OF THE EDISON PATENTS FOR ELECTRIC LIGHTING.

A PUBLIC notice was issued on May 23d, 1885, over the signature of the vice-president of the Edison Electric Light Co., in which it was stated that the patents of Mr. Edison "fully cover the exclusive manufacture, sale and use of *any and all* practical incandescent" lamps, and that the Edison company is prepared to "prosecute and punish to the full extent of the law all makers, sellers and users of incandescent lamps not fully authorized by it."

In an earlier official publication by the same company, dated July 27th, 1882, it was definitively stated that the following points, among others, were broadly covered by Mr. Edison's patents:—

1. An electric lamp having a continuous conductor (without regard to its material, resistance or mode of preparation) and an exhausted glass enclosing globe.
2. An electric lamp having a continuous carbon conductor (irrespective of its material, resistance or mode of preparation) and an exhausted glass enclosing globe.
3. A filament of carbon of high resistance secured to metallic conductors (*i. e.*, the leading-in wires).

It is proposed in the present article to make an examination of the three patents which appear to be regarded by the Edison company as the essential ones upon which these alleged exclusive rights are based. These are as follows:—

No. 223,898, dated January 27th, 1880.
No. 227,229, dated May 4th, 1880.
No. 265,777, dated October 10th, 1882.

Before proceeding to examine these three patents on their merits, it may be pertinent to remark that under the provisions of section 4,887 of the Revised Statutes of the United States, there would seem to be little doubt that they have already become public property in this country.

The text of the statute referred to is as follows:—

Every patent granted for an invention which has been previously patented in a foreign country, shall be so limited as to expire at the same time with the foreign patent, or if there be more than one, at the same time with the one having the shortest term.

It has been decided by the United States Courts that an American patent expires at the same time with a foreign patent, when issued there before it is issued here, though the American application was filed first, and though the foreign patent may afterwards be extended for an additional term of years.[1] This question first arose in reference to the effect of a prior Canadian patent in limiting the term of the American patent, and it was held that the expression, "patented in Canada," means the date of grant and issue, not the date of delivery to the patentee. In the Gramme case[2] the same doctrine was reaffirmed with respect to a prior Austrian patent which had been taken for one year, and subsequently extended for nine years, but had expired.

It is proper to state that the question involved in these two cases has yet to be passed upon by the Supreme Court. While we regard this law as an absurd relic of barbarism, and would be glad to see it swept from the statute books, we look for the needed relief to come from Congress and not from the Supreme Court.

The records show that the subject-matter of Edison's patent No. 223,898, of January 27th, 1880, was patented in Canada as No. 10,654 on November 17th, 1879, for a term of five years. Under the statute, therefore, this patent expired November 17th, 1884. The same invention was also patented in Italy for six years on December 6th, 1879.

The subject-matter of Edison's patent No. 227,229, of May 4th, 1880, was patented in Italy for six years on June 23d, 1879, and its term commenced to run on June 30th, 1879. Hence this patent, under the provisions of the statute, expired on the 30th of June, 1885.

The subject-matter of Edison's patent No. 265,777, of October 10, 1882, was patented in Austria, August 3, 1881, and it expired in that country, and consequently in the United States, on the 3d August, 1883.

Hence it appears that, under the provisions of the statute referred to, every one of these three so-called "fundamental patents" of Edison is now public property, and may freely be used by any one, so far as the Edison Electric Light Co. is concerned.

Leaving this aspect of the case out of consideration altogether, there would appear, moreover, to be good reason for the opinion that the patents are intrinsically invalid for want of novelty, or by reason of unpatentable subject-matter. As this subject is of considerable importance, it is proposed to discuss it at some length. The three patents will be considered separately, in the order of the dates on which they were respectively filed in the United States Patent Office.

UNITED STATES PATENT OFFICE.

Thomas A. Edison, of Menlo Park, New Jersey.

ELECTRIC LIGHT.

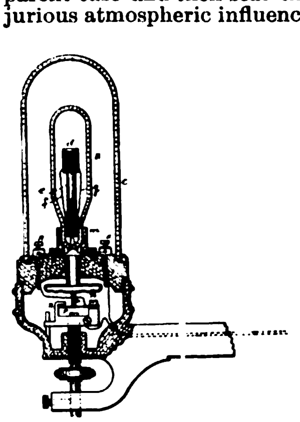
Specification forming part of Letters Patent No. 227,229, dated May 4, 1880. Application filed April 21, 1879.

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the State of New Jersey, have invented an improvement in electric lights (Case No. 176), of which the following is a specification.

When platina and other metals that fuse at a high temperature are exposed to high heat and then cooled in the atmosphere they are injured, so that they are not well adapted to use in electric lights for a long period of time.

I inclose the conductor that forms the electric candle in a transparent case and heat the same gradually to expel any gases from the material of the candle. I form a vacuum in the transparent case and then seal the same hermetically, so that all injurious atmospheric influences are avoided.



The invention further consists of a vacuum-receptacle made entirely of glass and sealed by melting the same in combination with an incandescent continuous conductor pyro-insulated.

The invention further consists in winding pyro-insulated wire upon a bottom of a compressed infusible substance, such as lime.

The invention further consists in placing the vacuum-bulb within another glass receptacle, also closed from the air, and employing the expansion of the air between the two receptacles due to the heat of the incandescent bobbin to produce a movement which shall disconnect the lamps from the electric circuit when its temperature is too great.

The drawing shows a section of the apparatus, in which B is the transparent bulb. This bulb is open at the smaller end and the burner *d* inserted, and the open end of the tube is placed in connection with a mercury vacuum-pump, the platina wires *g* and *f* passing through. The burner is connected with a battery and variable resistance coil while the vacuum is being made. The heat of the bobbin *d* is, in the course of one hour, brought gradually from the temperature of the air to vivid incandescence. When the vacuum is considered practically perfect the open end of the tube is melted and sealed. The platina wires passing through the glass are also sealed.

Thus I am enabled to obtain a nearly perfect vacuum, which is permanent, and at the same time give the platinum wire a new and unknown property of great value in electric lighting, which is, that a platina wire which melts in the open air at a point where it emits a light equal to 4 candles will, when operated upon as described, emit a light equal to 25 candles without fusion. The reason why the melting-point of the metal is thus raised is, that in the act of making the vacuum with the metal under heat all the gases which are contained in its pores are withdrawn, and when the receptacle is sealed cannot re-enter when cold; hence unequal and sudden expansions cannot take place and the wire is never cracked, but if left uncovered becomes as bright as the most polished silver—an appearance which cannot be given it in any other way. On the other hand, it is known that the metals of the platinum group have, in a surprising degree, the peculiar

1. Bate Refrigerator Co. *v.* Gillett, 22 Off. Gaz., 1,205.
2. Gramme Electrical Co. *v.* The Arnoux-Hochhausen Electric Co. *et al.*, 25 Off. Gaz., 193.

Digitized by Google

power of absorbing within their pores many volumes of gas, and it is the sudden expansion of this gas upon a sudden accession of heat that disrupts the wire and produces cracks, which extend nearly to its centre when the wire is brought to moderate incandescence in the open air. These cracks set up a great resistance to the passage of the current, and at these points become abnormally heated; hence the platina wire easily melts, whereas no such cracks are noticed when the wire has been operated upon in the vacuum and all its gases pumped out.

e is a cylinder, of lime, with a small spool on its extremity, on which the wire is coiled. About 30 feet of platinum or iridium wire coated with magnesia oxide is coiled upon the spool.

The wire may be of any size; but I prefer to use wire .005 of an inch in diameter, which will give a resistance when incandescent of about 750 ohms. By the use of such high resistant lamps I am enabled to place a great number in multiple arc without bringing the total resistance of all the lamps to such a low point as to require a large main conductor; but, on the contrary, I am enabled to use a main conductor of very moderate dimensions.

Another important point is gained by the use of lamps of high resistance, as the resistance of the wires leading from the main conductors may be of very moderate dimensions; hence can be placed in the pipes already used for gas, and at the same time effect a great saving in the cost of wire.

Still another point gained is, that the high resistance of the lamps allows all to be placed in multiple arc, which is the only method where the maximum economy is attainable, as the lamps, when connected to the circuit, draw from the central station just sufficient current to maintain it at the proper temperature, and if by accident or want of regularity in the main current the strength of the current should increase abnormally, the excess of heat sets the thermal regulator in motion and disconnects the lamp entirely from the circuit, thus stopping all further consumption of energy until the temperature of the lamp is reduced to its normal conditions. I will state that these changes are not perceptible to the eye; hence the lamp cannot consume any more energy than that required to cause it to emit a certain light.

No loss in economy occurs by using so large a resistance, because the loss of energy is proportionate to the radiating-surface exposed to the air and its temperature, and is independent of the resistance of the wire forming such surface.

m is a lime cup, into which the small end of the vacuum-burner is held. The platina wires pass under it to the binding-posts H K.

n is the thermal regulator, operated by the expansion of the air. When the temperature of the air between the bulbs becomes too great, the diaphragm bulges outward and the point *o* separates the spring *p* from R and disconnects the lamp from the circuit, where it remains until the temperature is reduced to the normal condition.

The spark upon the point is very small, as I employ constant field-magnets at the central station; hence the powerful sparks due to the secondary current set up by the weakening of the powerful field-magnet is avoided.

I will mention that the second globe, *c*, might be made entirely of glass, and the aneroid-diaphragm, provided with a platina tube, be sealed in the glass, or the aneroid itself be made of glass.

I am aware that an electric lamp has been made in which glass has been combined with other substances to form a case, and that efforts have been made to keep such case air-tight; but the changes of temperature have prevented the maintenance of a vacuum or the exclusion of the atmosphere. In my improvement the chamber containing the light is made entirely of glass, and I am able to obtain and maintain a vacuum, because there is no substance joined to the glass; hence the entire chamber can be hermetically sealed, and the conductors of metal passing through the glass and around which the glass is melted are so small as not to injure the glass by their expansion.

I am also aware that carbon has been heated in the presence of both liquid and gaseous materials for changing its character and adapting it to an electric light. In my present invention the gaseous materials contained in metallic wire are driven off by the action of heat evolved by an electric current while the wire is in a vacuum, so that the pores of the metal are not filled with any extraneous substance; but, on the contrary, the metal is solidified by the removal of extraneous matter and the pores closed.

In my application No. 166 I have set forth an electric lamp formed of pyro-insulated metal. I do not, therefore, claim the same herein.

I claim as my invention—

1. In an electric lamp, the combination, with a hermetically-sealed vacuum-chamber made entirely of glass of metallic conductors passing through the glass and around which the glass is melted, and an incandescent conductor placed in the electric circuit, substantially as set forth.

2. The method herein specified of treating metallic conductors for electric lamps, consisting in inclosing the conductor in a glass case, exhausting the atmosphere from such case, heating the conductor by an electric current, and then hermetically sealing such glass case, substantially as set forth.

3. The combination, in an electric lamp, of a hermetically-sealed vacuum-case made entirely of glass, conducting-wires passing through the glass and around which the glass is melted, and an incandescent body formed of a pyro-insulated wire and an infusible core for the same, substantially as set forth.

4. The combination of a transparent vacuum-case, a continuous conductor forming an electric candle, and a second transparent case forming a closed chamber, for the purpose set forth.

5. The combination of the conductor *d*, forming an electric candle, the transparent sealed case B, the transparent case C, inclosing the case B, and the thermostatic regulator *n o p* R, substantially as set forth.

EDWIN M. FOX.

The first and second claims of this patent are the only ones which are important to consider, the others being for obsolete details of construction.

The state of the art at the date when the application for this patent was made has an important bearing upon the question of its novelty. It will be necessary, therefore, to briefly review the results of some prior inventors in this line of work.

Perhaps the earliest mention of the incandescent electric light proper is in a paper by William Robert Grove, the inventor of the well-known Grove battery, in the *Philosophical Magazine*, third series, vol. xxvii., p. 442, from which the following is an extract:—

> The following was one of the apparatus which I used for this purpose, and by the light of which I have experimented and read for hours: A coil of platinum wire is attached to two copper wires, the lower parts of which, or those most distant from the platinum, are well varnished; these are fixed erect in a glass of distilled water, and another cylindrical glass over them, so that its open mouth rests on the bottom of the former glass; the projecting ends of the copper wires are connected with a voltaic battery (two or three pairs of the nitric acid combination), and the ignited wire now gives a steady light, or which continues without any alteration or inconvenience as long as the battery continues constant, the length of time being, of course, dependent upon the quantity of the electrolyte in the battery cells [vide Fig. 1].

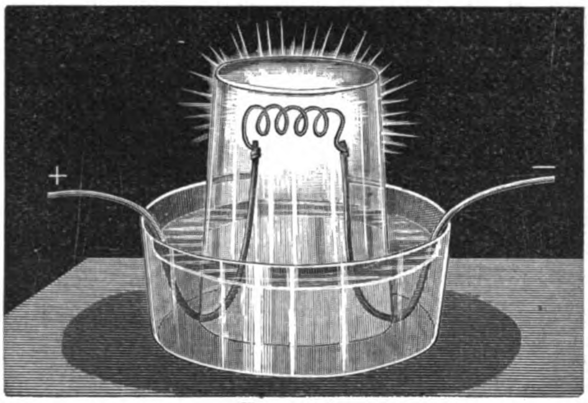

FIGURE 1.

According to the statement made in the paper, these experiments were made in 1840 and 1841, shortly after the invention of the nitric acid battery. The publication above quoted was made in 1845.

An American inventor named J. W. Starr, a resident of Cincinnati, devised, constructed and operated a lamp, which was patented in England, as a communication, by Edward A. King, November 4th, 1845 (No. 10,919), which was, in fact, a long step towards the realization of a practical incandescent lamp. Starr's lamp consisted of an air-tight glass tube, closed at its upper end, as shown in figure 2, and having one conducting wire hermetically sealed into the glass. A porcelain bar placed within the tube serves as a support for a slender carbon rod, the upper extremity of which is connected with the conducting wire at the top of the tube, and the lower extremity with the other.

The tube being filled with mercury and inverted, a Torricellian vacuum is formed above the mercury seal, so that

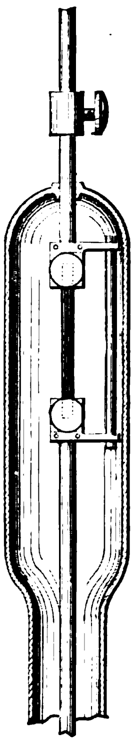

FIGURE 2.

the carbon when rendered incandescent by the passage of a current is entirely withdrawn from the influence of oxygen.

In 1847 Professor J. W. Draper, of New York, made a very interesting series of investigations on the heat and light evolved by platinum wires when traversed by powerful electric currents, and suggested that the currents might be regulated automatically.[3] The results described by Professor Draper some years afterwards attracted the attention of Professor Moses G. Farmer, then a resident of Salem, Mass., who was thereby led to attempt to make a practical application of Draper's results in an incandescent electric lighting system. Professor Farmer made a great number of experiments, relating not only to the construction of the lamp itself, but to the automatic control and regulation of the current. Among the substances tested for the purpose were aluminum, platinum, iridium, palladium, carbon, etc. Of all the metals, pure iridium was found to give the best results. The next best in order were alloys of iridium and platinum, and of platinum and palladium. Very satisfactory results were also obtained from carbon when enclosed in an atmosphere free from oxygen, as in the Starr lamp. In 1859, Professor Farmer constructed an apparatus for lighting the parlor of his house in Salem, which was actually used for that purpose every evening during the month of July of that year. This was probably the first instance in which a private dwelling house was ever lighted by electricity. The current was furnished by a Grove battery of six-gallon jars, 31 in number, placed in the cellar. Two incandescent lamps were placed in the parlor, one on each end of the mantelpiece, and these were connected to the battery in multiple arc. The switches for turning the lamps off and on were placed in a closet in another room. Figure 3 illustrates one of these lamps. It consists of a thin strip of platinum supported in metallic clamps formed of the blades of ordinary mechanical drawing-pens, to which the conducting wires were led through a hollow section of ornamental metallic gas-tubing, which formed a supporting standard of the lamp. The light emitted by each lamp was estimated to be equivalent to 32 candles. The results of this practical test showed that the incandescent light, although satisfactory in other respects, was much too costly for practical use, the expense being at least four times as much as that of an equal amount of light produced by gas.

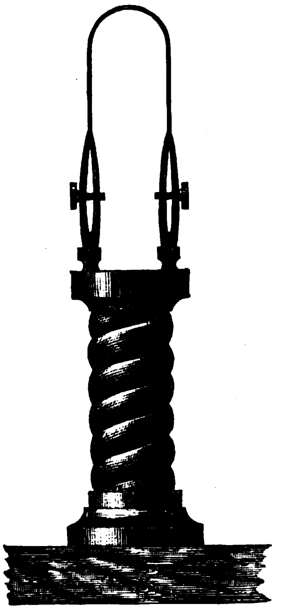

FIGURE 3.

In 1865, the thermo-electric battery, in which electricity is generated directly by the heat of coal or other combustible substance, was brought prominently into notice. In the hope that this invention might furnish a cheap source of electric energy, Professor Farmer again turned his attention to the problem of electric illumination. Between 1865 and 1868 he was almost constantly engaged in experimenting in incandescent lamps and electrical generators. During this time he had five such lamps connected in multiple arc. The electric current in the system was controlled by an automatic regulator, so sensitive as to be affected even upon the slight cooling of the lamps by a current of air produced upon the opening or shutting of a door of the room in which the apparatus was placed. This apparatus was on exhibition in Boston until 1868, when it was accidentally destroyed by fire. The form of lamp employed by Professor Farmer in most of these experiments is shown in figures 4 and 5.

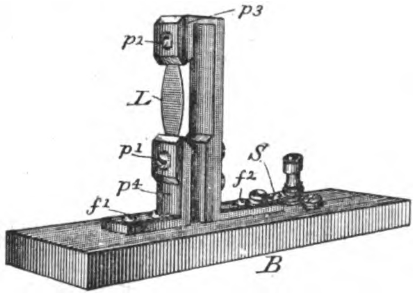

FIGURE 4.

FIGURE 5.

It is not necessary to more than mention the incandescent lamps of Lodyguine in 1873, and Konn and Kosloff in 1875, as these inventions, though not without interest, contributed little, if anything, towards the ultimate solution of the problem of incandescent electric lighting.

In 1877 and 1878, Mr. William Crookes, of the Royal Society, published an account of a remarkable series of experiments on radiant energy. Among the illustrative apparatus which he constructed and employed was a little instrument which he termed the radiometer, which may be briefly described as a small revolving wheel provided with vanes or paddles of mica, poised upon a delicate pivot within a highly exhausted and hermetically sealed glass bulb. Mr. Crookes showed that a paddle-wheel so constructed could be maintained in continuous revolution by the mechanical force of light alone. In an account of some of his experiments, published in London *Engineering*, April 19th, 1878, a description and illustration of one of these radiometers is given as follows:—

One of the instruments employed is that shown in fig. 6, in which is suspended in the ordinary way upon a needle point a four-armed radiometer, carrying rectangular vanes of clear mica, *b b*, set on an angle with the horizontal arms like the vanes of a smoke-jack. A short distance below this fly is fixed in a horizontal plane a circular loop of platinum wire, *c*, *c*, the two ends of which pass through the bulb, *being hermetically sealed into the glass*, and finish in the terminals + and —, by which the platinum ring can be placed in circuit with a voltaic battery, *and thus rendered incandescent.*

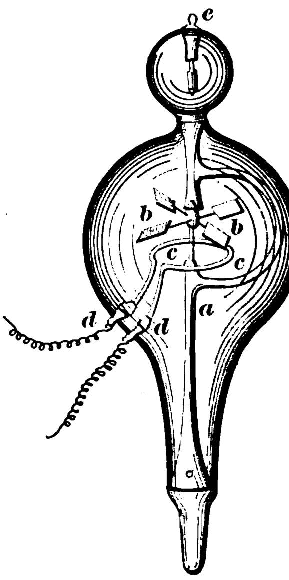

FIGURE 6.

For determining the pressure, the whole apparatus was connected by glass tubing and fused joints to a very perfect Sprengel mercury pump, designed and constructed by Mr. C. H. Gimingham, fitted with apparatus for obtaining a chemical vacuum by different absorptions of different substances contained in the residue gases, as well as for eliminating from the same all traces of aqueous vapor, and having attached to it McLeod and barometric gauges for measuring the pressure at different degrees of exhaustion. For the observation of the appearance of the electric discharge—a very valuable indication of the progress of the exhaustion—there was attached to the apparatus a vacuum tube in gaseous connection with its interior, and in which two platinum electrodes were placed very close together. In addition to these accessories, there was a small torsion balance carrying at one end a standard disc of blackened mica, and at its centre a small mir-

3. *Silliman's Journal* (2d Series) lv., 1847. Phil. Mag., May, 1847.

Digitized by Google

ror, by which its angular displacement could be measured by the movement of a spot of light along a scale, and lastly, there was the special apparatus, which has been described, containing the rotating disc and vanes, and the platinum ring which, by being put into and out of circuit by a Morse key with a voltaic battery, through various resistances could be rendered either just warm or heated through various degrees of incandescence almost up to its temperature of fusion ; and when it is remembered that provision had to be made for the introduction of various gases into the apparatus previous to the process of exhaustion, it will be readily understood that, although the whole arrangement was as simple as its requirements would admit, still it was considerably elaborate ; from its necessary complexity, it required the utmost skill to construct, and it was impossible to be carried about.

In order to show the phenomena which have been described to the members of the Royal Society, in illustration of his paper, Mr. Crookes had several instruments identical in construction to that represented in figure 6, but containing gaseous vacua of different degrees of exhaustion, one being at atmospheric pressure, and the others at the pressures at which the more remarkable effects are observed, and to which we have referred. The effects, which were very interesting, were made apparent to the audience by an image of the instrument under experiment being projected upon a screen by means of a sciopticon lantern.

The influence of the residual gas upon the radiation of heat was beautifully illustrated in these experiments by the greater or less degree of incandescence of the platinum ring with the same battery power at different degrees of exhaustion of the gas surrounding it. The same battery power which would almost fuse the wire in the bulb at higher degrees of exhaustion was capable of only just reddening it at atmospheric pressure, so that, in order to obtain the same temperature of the platinum wire in vacua of different degrees of attenuation, it is necessary to vary the battery power, or what produces the same result, to interpose in the circuit greater resistance as the vacuum becomes more perfect. The comparative temperatures of the rings at different exhaustions were very remarkably illustrated when three instruments, differently exhausted, were joined up in the same circuit, so that the electric current had absolutely the same strength in each case. When this was done the ring in the normal atmospheric pressure was black, that at a higher exhaustion was just red, *while the coil in the still more attenuated medium glowed with incandescence like a small electric lamp.*

Several of these bulbs, sealed up at different degrees of exhaustion, were exhibited at a soiree of the Royal Society, on the evening of April 5, 1876, by Mr. Crookes, and attracted much attention.

A comparison of this apparatus with that shown in the drawings of Edison's patent, especially in view of the prior researches of Grove, Draper, Starr, and Farmer, will enable any person to judge for himself of the degree of essential novelty which is exhibited in the device on which Edison's claims are founded.

UNITED STATES PATENT OFFICE.

Thomas A. Edison, of Menlo Park, New Jersey.

ELECTRIC LAMP.

Specification forming part of Letters Patent No. 223,898, dated January 27, 1880. Application filed November 4, 1879.

To all whom it may concern:

Be it known that I, Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, have invented an Improvement in Electric Lamps, and in the method of manufacturing the same (Case No. 186), of which the following is a specification.

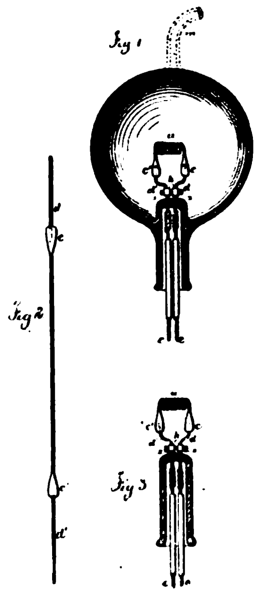
The object of this invention is to produce electric lamps giving light by incandescence, which lamps shall have high resistance, so as to allow of the practical subdivision of the electric light. The invention consists in a light-giving body of carbon wire or sheets coiled or arranged in such a manner as to offer great resistance to the passage of the electric current, and at the same time present but a slight surface from which radiation can take place.

The invention further consists in placing such burner of great resistance in a nearly perfect vacuum, to prevent oxidation and injury to the conductor by the atmosphere. The current is conducted into the vacuum-bulb through platina wires sealed into the glass.

The invention further consists in the method of manufacturing carbon conductors of high resistance, so as to be suitable for giving light by incandescence, and in the manner of securing perfect contact between the metallic conductors or leading-wires and the carbon conductor

Heretofore light by incandescence has been obtained from rods of carbon of 1 to 4 ohms resistance, placed in closed vessels, in which the atmospheric air has been replaced by gases that do not combine chemically with the carbon. The vessel holding the burner has been composed of glass cemented to a metallic base. The connection between the leading-wires and the carbon has been obtained by clamping the carbon to the metal. The leading-wires have always been large, so that their resistance shall be many times less than the burner, and, in general, the attempts of previous persons have been to reduce the resistance of the carbon rod. The disadvantages of following this practice are, that a lamp having but 1 to 4 ohms resistance cannot be worked in great numbers in multiple arc without the employment of main conductors of enormous dimensions; that, owing to the low resistance of the lamp, the leading-wires must be of large dimensions and good conductors, and a glass globe cannot be kept tight at the place where the wires pass in and are cemented; hence the carbon is consumed, because there must be almost a perfect vacuum to render the carbon stable, especially when such carbon is small in mass and high in electrical resistance.

The use of a gas in the receiver at the atmospheric pressure, although not attacking the carbon, serves to destroy it in time by "air-washing," or the attrition produced by the rapid passage of the air over the slightly coherent highly-heated surface of the carbon. I have reversed this practice. I have discovered that even a cotton thread properly carbonized and placed in a sealed glass bulb exhausted to one-millionth of an atmosphere offers from 100 to 500 ohms resistance to the passage of the current, and that it is absolutely stable at very high temperatures; that if the thread be coiled as a spiral and carbonized, or if any fibrous vegetable substance which will leave a carbon residue after heating in a closed chamber be so coiled, as much as 2,000 ohms resistance may be obtained without presenting a radiating-surface greater than three-sixteenths of an inch; that if such fibrous material be rubbed with a plastic composed of lamp-black and tar, its resistance may be made high or low, according to the amount of lamp-black placed upon it; that carbon filaments may be made by a combination of tar and lamp-black, the latter being previously ignited in a closed crucible for several hours and afterward moistened and kneaded until it assumes the consistency of thick putty. Small pieces of this material may be rolled out in the form of wire as small as seventy-one thousandths of an inch in diameter and over a foot in length, and the same may be coated with a non-conducting non-carbonizing substance and wound on a bobbin, or as a spiral, and the tar carbonized in a closed chamber by subjecting it to high heat, the spiral after carbonization retaining its form.



All these forms are fragile and cannot be clamped to the leading-wires with sufficient force to insure good contact and prevent heating. I have discovered that if platinum wires are used and the plastic lamp-black and tar material be molded around it in the act of carbonization there is an intimate union by combination and by pressure between the carbon and platina, and nearly perfect contact is obtained without the necessity of clamps; hence the burner and the leading-wires are connected to the carbon ready to be placed in the vacuum-bulb.

When fibrous material is used the plastic lamp-black and tar are used to secure it to the platina before carbonizing.

By using the carbon wire of such high resistance I am enabled to use fine platinum wires for leading-wires, as they will have a small resistance compared to the burner, and hence will not heat and crack the sealed vacuum-bulb. Platina can only be used, as its expansion is nearly the same as that of glass.

By using a considerable length of carbon wire and coiling it, the exterior, which is only a small portion of its entire surface will form the principal radiating-surface; hence I am able to raise the specific heat of the whole of the carbon, and thus prevent the rapid reception and disappearance of the light, which on a plain wire is prejudicial, as it shows the least unsteadiness of the current by the flickering of the light; but if the current is steady the defect does not show.

I have carbonized and used cotton and linen thread, wood splints, papers coiled in various ways, also lamp-black, plumbago, and carbon in various forms, mixed with tar and kneaded so that the same may be rolled out into wires of various lengths and diameters. Each wire, however, is to be uniform in size throughout.

If the carbon thread is liable to be distorted during carbonization it is to be coiled between a helix of copper wire. The ends of the carbon or filament are secured to the platina leading-wires by plastic carbonizable material, and the whole placed in the

Digitized by Google

carbonizing-chamber. The copper, which has served to prevent distortion of the carbon thread, is afterward eaten away by nitric acid, and the spiral soaked in water, and then dried and placed on the glass holder, and a glass bulb blown over the whole, with a leading-tube for exhaustion by a mercury-pump. This tube, when a high vacuum has been reached, is hermetically sealed.

With substances which are not greatly distorted in carbonizing, they may be coated with a non-conducting non-carbonizable substance, which allows one coil or turn of the carbon to rest upon and be supported by the other.

In the drawings, figure 1 shows the lamp sectionally, *a* is the carbon spiral or thread. *c c'* the thickened ends of the spiral, formed of the plastic compound of lamp-black and tar. *d d'* are the platina wires. *h h* are the clamps, which serve to connect the platina wires, cemented in the carbon, with the leading-wires *x x*, sealed in the glass vacuum-bulb. *e e* are copper wires, connected just outside the bulb to the wires *x x*. *m* is the tube (shown by dotted lines) leading to the vacuum-pump, which, after exhaustion, is hermetically sealed and the surplus removed.

Figure 2 represents the plastic material before being wound into a spiral.

Figure 3 shows the spiral after carbonization, ready to have a bulb blown over it

I claim as my invention—

1. An electric lamp for giving light by incandescence, consisting of a filament of carbon of high resistance, made as described, and secured to metallic wires, as set forth.

2. The combination of carbon filaments with a receiver made entirely of glass and conductors passing through the glass, and from which receiver the air is exhausted, for the purposes set forth.

3. A carbon filament or strip coiled and connected to electric conductors so that only a portion of the surface of such carbon conductors shall be exposed for radiating light, as set forth.

4. The method herein described of securing the platina contact-wires to the carbon filament and carbonizing of the whole in a close chamber, substantially as set forth.

Signed by me this 1st day of November, A. D. 1879.

Witnesses: THOMAS A. EDISON.
S. L. GRIFFIN,
JOHN F. RANDOLPH.

The important claims of the above patent are the first and second, the others being merely for special details and methods of construction. The application was filed November 4, 1879. Another and subsequent application was filed by Edison on December 11, 1879, one claim of which was for "the incandescent conductor for an electric lamp formed of carbonized paper." On January 9, a little less than a month afterwards, a joint application for a patent for electric lighting was filed by Messrs. W. E. Sawyer and A. Man, claiming, among other things, substantially the same invention. These two applications were put in interference by the Commissioner of Patents; a large amount of testimony was taken on both sides, and the Examiner of Interferences decided Sawyer and Man to be the prior inventors of the contested subject-matter. This decision was reversed by the Board of Examiners-in-Chief, but was appealed to the Commissioner of Patents in person, who rendered a decision October 8, 1883, affirming the decision of the Examiner of Interferences, and awarding priority to Sawyer and Man.[4] After several attempts to obtain a reopening and rehearing of the case on its merits, the original decision was reaffirmed by Commissioner Butterworth, and a patent for the invention of Sawyer and Man was issued on May 12, 1885.[5] The testimony taken in the interference proceedings shows that Edison did not make the invention described in patent No. 223,898 until October, 1879, while Sawyer and Man commenced their experiments in electric lighting in February, 1878; they had the invention in a rude form as early as March, 1878, and in a complete and operative form in September or October, 1878; thus anticipating the completion of Edison's invention by nearly a year. The testimony showed that Sawyer and Man at this date had lamps in operation that lasted for hours, and even days, consisting of an illuminating chamber made entirely of glass, and hermetically sealed, and from which the air had been exhausted, and having metallic circuit-conductors passing through the glass walls of the chamber, and hermetically sealed therein, and an illuminating or incandescent conductor included in a circuit within said chamber, in the form of an arc or loop made from carbonized fibre or textile material.

It will be seen that the invention set forth in the first claim of Edison's patent, in so far as it differs from the prior invention of Sawyer and Man, differs only in the form and dimensions of the parts. A "filament" of carbon differs from a "strip" of carbon, as used by Sawyer and Man, only in that the former is longer and thinner; so also Edison's metallic wires, to which the carbon is secured, differ from those of Sawyer and Man only in being of less thickness. These differences, it is true, are in practice of the utmost importance, as they enormously increase the commercial efficiency of the lamp, but it may well be doubted whether any exercise of the faculty of invention is required to pass from one to the other. It could certainly have required no invention, in the state of the art in 1879, to know that the resistance of the paper carbon could be largely increased by making it long and thin—that is to say, in the form of a filament—and it certainly cannot be patentable *per se* to make a filament of great resistance which had heretofore been made of small resistance, if for no other reason, because the term "high resistance" in the specification has no determinate meaning. Edison's specification states that lamps not exceeding four ohms resistance are of "low resistance," but how much this figure must be increased to render them of high resistance we are not informed. This claim, therefore, so far as it depends upon the high resistance feature, would appear to be void for uncertainty.

Precisely the same reasoning applies to the subject-matter of the second claim. The invention claimed is distinguishable from the anterior one of Sawyer and Man only by the use of the term "filament." If the carbonized paper strip of Sawyer and Man be increased in length and diminished in cross-section, by what criterion is it to be determined when it ceases to be a "strip" and becomes a "filament?"

It is difficult to understand why the application for this patent was not also included in the interference to which we have referred, for it seems certain that, so far as the invention or the subject-matter of the patent is embodied in the first two claims, it is not distinguishable from that of Sawyer and Man, which was filed a year in advance of it. No one can question that the Edison lamp is both mechanically and commercially a vast improvement over its predecessor; but it is no less true that the features which constitute it such an improvement appear to be precisely the ones which the patentee has omitted to claim.

UNITED STATES PATENT OFFICE.

Thomas A. Edison, of Menlo Park, New Jersey, Assignor to the Edison Electric Light Company, of New York, N. Y.

METHOD OF TREATING CARBONS FOR ELECTRIC LAMPS.

Specification forming part of Letters Patent No. 265,777, dated October 10, 1882.

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful method of treating carbons for electric lamps (Case No. 275); and I do hereby declare that the following is a full and exact description of the same.

In the manufacture of my incandescing electric lamps, having for the continuous incandescing conductor a flexible carbon filament of high resistance, I have found that there is a considerable quantity of air, gas, and aqueous vapor occluded in the carbon filament and the clamps, which are not removed from the lamp by the action of the pump, but have to be driven off by raising the carbon filament to incandescence by the passage of an electric current therethrough.

In patent No. 227,229, granted to me May 4, 1880, the method is described of driving the air from a metallic incandescing conductor by the heat of the conductor when raised to incandescence by the passage of an electric current therethrough. In applying this method to a carbon filament, however, some changes have to be made, occasioned by the increased quantity of air, gas, and aqueous vapor occluded by the carbon filament, and also by the fact that the air has to be driven from the enlarged ends of the filament and from the metal clamps wholly by conduction of heat from the incandescent body of the filament.

4. The decision in full may be found in 25 Off. Gaz., 597.

5. For copy of this patent, see ELECTRICIAN AND ELECTRICAL ENGINEER, p. 233, this volume.

Digitized by Google

these changes in the method consist principally in maintaining the incandescence of the carbon filament for a longer period than with a metallic incandescing conductor, and in raising the carbon filament gradually to a higher degree of incandescence than with the metallic conductor. With the carbon filament the incandescence finally produced in the process of exhaustion is always higher than the degree of incandescence to which the filament will be raised in use. With the carbon filament (in this respect differing from the metallic conductor) it is desirable that greater flexibility should be given the filament than it would have if the lamp were exhausted simply by the action of the pump, so that the carbon filament can withstand, without fracture, the jars to which it will be subjected in handling and transportation previous to the use of the lamp. This additional flexibility is given the carbon filament by the passage of an electric current therethrough, the operation being simultaneous with that of driving out the occluded air, gas, and aqueous vapor. It is also desirable to fix the shape of the carbon filament during the manufacture of the lamp, so that the character of the lamp can be determined, since some of the filaments are warped or bent more or less to one side or the other when raised to incandescence; but by raising the carbon filament to higher incandescence than that to which it will be raised in use the shape of the filament will be fixed and determined, and will not be changed by the future use of the lamp. This operation, which is peculiar to the carbon-filament operation, is also simultaneous with that of driving out the occluded air, gas, and aqueous vapor.

In carrying out the invention the parts of the lamp are assembled and united as described in my application No. 22,301, of even date with this application, or in any other suitable manner. The lamp is then attached to the exhausting apparatus (a Sprengel drop-pump), and when the proper high degree of exhaustion has been obtained an electric current is passed through the lamp, and by cutting resistance out of circuit the filament is gradually raised in incandescence. The filament is kept for some time at a medium incandescence, the operation of the exhausting apparatus being meanwhile continued. The filament is then raised to a much higher incandescence by the cutting out of more resistance, until the air and gas and aqueous vapor have been driven from the enlarged ends of the filament and the clamps, which can be readily determined by the disappearance of a blue or violet color which is seen at the clamps while the gas and vapor are being driven off. This high incandescence is considerably higher than that at which the lamp is designed to be used, it being from 30 candle-power upward in a lamp designed to give 16 candle-power.

What I claim is—

1. The method of treating the carbon filament of an incandescing electric lamp, consisting in raising such carbon filament to incandescence during the latter part of the process of exhausting the lamp-globe, whereby the air and gas are driven from the carbon filament and the flexibility of the filament is increased, substantially as set forth.

2. The method of treating the carbon filament of an incandescing electric lamp, consisting in raising such carbon filament to a higher incandescence than that at which it is designed to be used during the latter part of the process of exhausting the lamp-globe, whereby the air and gas are driven from the carbon filament and from its enlarged ends and clamps, and the flexibility of such filament is increased and its shape fixed, substantially as set forth.

This specification signed and witnessed this 11th day of December, 1880.

Witnesses: THOMAS A. EDISON.

H. W. SEELY,
WM. CARMAN.

It will be observed that the subject of the first claim is a method of treating the carbon filament of an incandescent electric lamp. This "method" is in reality precisely the same as that already described in Edison's prior patent 227,229, quoted above, as well as in the extract describing the experiments of Professor Crookes, and differs only in respect to the material to which the treatment is applied. An attempt has been made in the specification without much success, to draw a distinction between the two methods, the main point insisted upon being that the carbon filament is to be raised during treatment to a higher incandescence than that at which it is designed to be used. This would seem to be a somewhat slender distinction on which to base a patent. Suppose another party makes use of the process, and in treating the filaments makes use of a current of precisely 1 ampère and no more, labels his lamps accordingly, and then says to the consumer: "These lamps are designed to be run with a current of 1 ampère, but we advise you to use a current of not more than $\frac{95}{100}$ of an ampère, and then your lamps will last so much the longer." Is the patent infringed or not?

A particular process which has been used in a certain manner for a certain purpose, namely, to drive out the occluded gases contained in an incandescent conductor of metal, does not become a new process when applied in the same manner to drive out the occluded gases from a metalloid. How can it be anything more than a double use of the old process? The old process having, moreover, been described in a patent issued several months before the application for the present patent was filed, to say nothing of the description of Crookes's experiment, cannot legally be repatented under a second application. There is much reason, therefore, to anticipate that the result of the litigation which has been commenced by the Edison Electric Light Co. will rather tend to disestablish than to establish their patents, and it seems extremely probable that the ultimate conclusion of the litigation will be to throw open to the public a number of the most important inventions and processes having to do with incandescent electric lighting.

IMPROVED SECONDARY BATTERY.

At a recent meeting of the Berlin Physical Society, Dr. Kalischer described a new secondary battery, intended to overcome the disadvantages of the usual accumulators—namely, that the sheet of lead used as anode was very soon destroyed. This object he is said to have attained by adopting a very concentrated solution of nitrate of lead as electrolyte, and iron as anode. The iron, on being immersed in the solution of lead, became passive, and resisted every corroding effect of the fluid; in other respects the peroxide of lead on the electric charge became deposited at the anode as a very firm coherent mass, enveloping and protecting the iron on all sides. The charge was continued till the greater part of the nitrate of lead was decomposed, a condition which was marked by the occurrence of a greater development of gas at the anode. At the beginning of the charge all development of gas must be avoided as otherwise the peroxide of lead, or, more correctly, the hydrate of peroxide of lead, became covered with bubbles. As cathode a sheet of lead was used, but it was attended by two disadvantages. In the first place the lead, during the charge, separated itself at the cathode into long crystal threads, which soon passed through the fluid and produced short closing (of the current). In the second place the nitric acid, which remained in the fluid after the separation of the lead, acted very powerfully on the sheet of lead. Both disadvantages Dr. Kalischer avoided by amalgamizing the cathode. This accumulator of iron, concentrated solution of nitrate of lead, and amalgamized lead, yielded, after the electric charge, which could be carried out without any special preparations, a current of about two volts; after about six hours' discharge, however, the electromotive force sank to 1.7 volts, but, on the battery being left to itself for 24 hours, it became a little increased. According to the measurements hitherto taken, the functions of this accumulator were satisfactory. An attempt to substitute sulphuric manganese for nitric lead in this battery did not answer the purpose, as the peroxide of manganese separated itself, not in a continuous layer, but in loose scales.

MEASURING THE CANDLE-POWER OF A LIGHT.

The candle-power of a light may be approximately calculated by comparing the shadow cast by a rod in the light of a standard candle with the shadow cast by the light to be tested. By moving the latter toward or away from the rod a point will be reached at which the shadow cast by both lights will be of the same intensity. The intensities of the two lights are directly proportional to the squares of their distances from the shadows, *i. e.*, suppose the light to be tested is three times the distance of the candle, its illuminating power is nine times as great.

THE DISTRIBUTION OF ELECTRICITY.[1]

In the last lecture I was engaged in describing the different methods which have been used to apply what is called the multiple arc system of electric lighting. The multiple arc system is a system in which there are one positive and one negative lead between which the lamps are placed. I think that we succeeded in arriving at several very general conclusions which simplify the consideration of the manner of laying mains a great deal. I think I am right in saying that in the past the practice of designing mains has been to a certain extent haphazard; the mains have been selected a little at random, and then, perhaps, afterwards adjusted to a slight extent; but there has not been that thorough calculation and estimating of the effects which could be done by calculation, and in consequence of that there have been some grievous failures in electric lighting on the multiple arc system. I think we arrived at one or two important generalizations which must be accepted as necessary for economy, and in such a system—the multiple arc system—the amount of copper used in our mains is so enormous that every one must admit that economy is the first consideration, and that all engineering difficulties that there may be must be met by the engineer as difficulties which can be conquered. The most important results which we have arrived at were, I think, pretty clearly shown by illustration by this diagram of the city of Chicago, as we chose to call it, in which it was shown that, in order to have good distribution, there must be no great variation of pressure in the mains, electric pressure in the mains corresponding, as you will remember, exactly with hydraulic pressure if it were a service of water; and in order to prevent our having too great a variation of pressure in different parts of the district, or in the same district at different periods of the night, when the consumption over the district varies, it is necessary, as I showed by means of this diagram, to have a large number of distributing boxes with figure mains, trunk lines of conductors coming to these distributing boxes and feeding them, and each one of these distributing boxes then serving to light up a certain space, which in this diagram is essentially a triangular space. And I also gave you the rules for determining what is the size of the district which may be lighted up by such a distributing box, and I think every one here will agree with me that the limit was very confined indeed compared with the general ideas which prevailed as to the number of distributing boxes which are required; that is to say, that, upon the assumption upon which we have been going of the size of conductor required to carry a certain current, we concluded it would be necessary to have the distributing boxes so close that no lamp should be at a greater distance than 124 yards from the distributing box. Another important point which has been, I think I may safely say, altogether neglected in all schemes which have been hitherto issued for distribution of electricity from central stations is this: that the distributing box, the point from which the distribution takes place, must be closer to the central station than any of the lamps which are fed by that distributing box. As a general rule, the distributing box has been put in the centre district which it feeds, and that is a mistake; it ought to be nearer the central station than any of the lamps which it feeds. I gave you also in the last lecture some account of the relative cost of different systems of lighting in the multiple arc way, and it was found that, by introducing a large number of distributing boxes in this way, the cost was very materially reduced; but, at the same time, the cost was very great even with these distributing boxes. And the cost may be divided into two parts: first, the cost of the supply wires, the conductors which are supplying the electricity from each distributing box to the houses, which are represented by the square lines round each block of buildings there (fig. 1, p. 222); and secondly, there is the expense of the feeders, the conductors going up to the distributing boxes. Now when we increase the size of our district to any considerable extent, the cost of these feeders, these trunks which carry the electricity to the distributing boxes, is far greater than the cost of the supply system of conductors. If there be a means of reducing the cost in this way, that is to say, any way of cutting out these feeding conductors, that will be a very great economy indeed.

SMALLER CONDUCTORS AND HIGHER POTENTIAL.

This evening I will leave altogether apart the system of multiple arc lighting, which is the system which has been almost universally adopted in the past, and I shall speak this evening about the different systems which have been proposed and partly carried into effect for using higher pressure in the mains. The work which is done by a certain number of lamps is a perfectly definite amount of work, and it is measured by the product of the pressure of the electricity—the product of the quantity of the electricity which flows. If we increase the pressure, we diminish the quantity of electricity that flows; that is to say, we diminish the current; and if we diminish the current, we can diminish the size of our conductors.

Now a great deal has been talked about the danger of introducing high pressures in electric distribution. I think that I shall find general agreement among competent people when I say that a great deal of what has been talked in this way is pure nonsense, and that high pressures are not in the least more dangerous than our present systems of illumination; that if we have to bring high pressures of electricity through a district, those pressures are confined to the wires, and it is only in the case where there is disgraceful negligence of duty, and a disgraceful leakage towards the earth in some part of the system, that it is possible for anybody to receive a dangerous shock from the wires of such a system. The wires which conduct the electricity into a house of any of these high potential schemes can never have a greater difference of pressure between them than what is required for the lamp; that is, in the present state of affairs, something like 100 volts. We will say that is the highest pressure there can exist between the two wires, and it seems almost incredible that there should ever be allowed to be a leak in the system so great that when a person touches one of the wires he should have a high current flowing through his person which would be dangerous. If we are to abolish the idea of using high potentials simply because of this vague notion that some time a shock might be experienced, we might as well abolish the whole system of gas lighting, because it is possible that people can go into rooms where there is a leakage of gas with a lighted candle. The danger from gas is infinitely greater than that which can ever come from high potential electricity, and the difficulty of detecting a leakage of gas is likewise infinitely greater than the difficulty of detecting a leakage of electricity. A properly organized system of distribution of electricity at high potential would render a severe shock to any person absolutely impossible, and that is the point which needs to be dwelt on very strongly at present, because so much has been talked, and so much nonsense has been talked, about the dangers of high potentials.

I have often found a great convenience in describing the effects of electricity and the systems of distribution by reverting to the analogy of water pressure, and, I think, those of you here who are not deeply conversant with the subject of electrical engineering will, perhaps, be assisted by a few words of reference to the analogy of water pressures. At present we see through different parts of London pipes being laid for supplying power by means of water at high pressure. This water is utilized in motors or turbines, through which the water passes. The water pressure is remarkably analogous to the pressure of the electricity in our mains; the turbines or other motors which

1. Cantor Lecture, delivered at the Society of Arts, by Professor George Forbes, February 16, 1885.

Digitized by Google

are used to develop the power have remarkable analogy to the incandescent lamps or the arc lamps, or the electric motors which may be used with a system of distribution. Now, in the manner of laying pipes which we have all observed in the streets of London, all these turbines or water engines are connected directly on to the same set of pipes; in other words, they are all connected in multiple arc, as we would say in electric language. But it would be quite possible to conceive of two turbines connected together in series; that is to say, with a very high pressure in the mains first driving through one of these turbines, and then the outflow of water from that turbine still admitting of considerable high pressure to second turbine, which it should work with the superabundant pressure which should exist. This is exactly analogous also to the electric system of distribution in series; and this will be clear by examination of this diagram, fig. 1, the dynamo machine

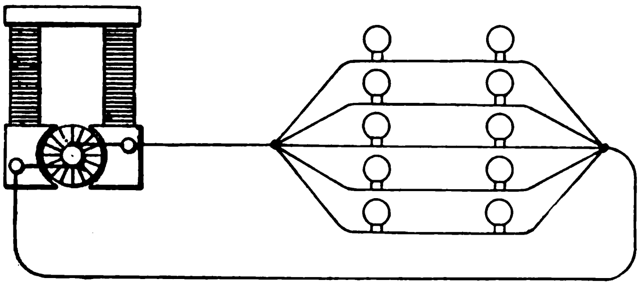

FIGURE 1.

with the two leads coming from it, and here are a number of circuits, each circuit having two lamps in series. This is exactly equivalent to a main to come along here, split into a number of water pipes with two turbines put in series. It follows that the pressure of water required to drive these two turbines is double the pressure required to drive the one. So it is exactly the same in electric distribution. We simply have to increase the pressure when we put a large number of lamps in series.

THE USE OF SECONDARY BATTERIES.

Now, there are several different ways in which high potentials can be used effectively and with economy. I will begin with mentioning the probable future which there may be in the application of secondary batteries. We often hear it remarked that the present systems of electric distribution are weak in some points, and that if only a system of secondary batteries were introduced, everything would be clear, and there is no doubt that, by introducing secondary batteries, a great deal of facility is given to the scheme. In the first place, you can have a much smaller engine power, much smaller dynamo power, because your dynamos can be working the whole day charging these accumulators, and only used for supply when it is required. In the second place, you can put your secondary batteries all in series over a large district, and charge them up all in series, and then discharge them each to its local district, a small number at a time, and a small number at one place. In this way, by using high potentials, of course we should use small currents. In the hydraulic analogy, by using high pressures, we require a smaller volume to flow, and therefore we should require smaller conductors, and consequently there would be a saving in laying down our copper. This is perfectly true, and there is not the slightest doubt a secondary battery system is of the utmost value, and would help us enormously. But at the present moment there are several difficulties in the way of introducing secondary batteries like this; and the first is, perhaps, the most fatal one, and that is, that we have no secondary battery. I do not mean to say that a great deal has not been done in the last four years in improving secondary batteries; it is my firm belief that a very great deal has been done even in the course of the last year in improving secondary batteries; but at the present time we have not sufficient confidence in the action of secondary batteries to justify any engineer in depending upon them in designing a scheme of distribution. But I must say that there is a great probability of something being done in this direction, because there is such a vast amount of intellect in the whole world being devoted to this particular line, trying to perfect it; and already I have seen such enormous improvements in secondary batteries of late that I cannot help thinking that very likely soon we shall arrive at something much more near perfection; and for this very reason I consider it is of the utmost importance that engineers should consider all such schemes which enable them to use high potentials, because, even though at the present time such a scheme as that introduced is imperfect to a certain extent, those schemes which lay down small wires for using with high potentials are the very schemes which will become applicable when the secondary battery is really a commercial thing in our possession; and, therefore, any person who has at the present moment to lay down a large system of lighting with the multiple arc system would perhaps find in the course of a year or two that the whole of this enormous cost of copper he had laid down would be utterly wasted, because some discovery which had been made would enable him to use smaller conductors. For this reason I consider, in designing a scheme of electrical distribution, an engineer should consider the great importance of a probable discovery in the way of secondary batteries.

There has been one large experiment in the way of secondary batteries made at Colchester, and I have got diagrams here showing schemes of electrical distribution. With respect to the diagram at the other end of the room, which was referred to in the first lecture (fig. 1, p. 182), I would simply say, if you have troughs, or good-sized channels in which your conductors are laid, there is very little difficulty about your insulation; with a good branch system and plenty of room the engineering difficulties are comparatively trivial, as long as you will remember the facts which I pointed out in my first lecture, that you are not to trust to your insulating material as the support for the conductor. Your conductor must be supported by a substance capable of supporting it, not by a bituminous compound through which the conductor will sink in the course of ages. But there are no engineering difficulties if you are able to have a trough for conducting your wires, and I am perfectly of opinion that if you have the mains laid down in that way, you can use your 5,000 volts with perfect facility, and there will be no danger, and with proper tests regularly made, such a system would not only be possible, but perfectly safe. With respect to this long diagram, fig. 2—rocking switch, it shows the arrangements which are made at Colchester by the South Eastern Brush Co. for distributing their electricity. The dynamos with the charging mains act through what is called a rocking switch into the secondary batteries. Now, in this supply system, first we have charging mains coming to the secondary batteries situated in different districts through the town, and then from the secondary batteries we have service mains going away to different houses which are to be supplied, and this rocking switch is controlled by what is called the master cell, which is simply a cell with a diaphragm, so that when the ebullition of gas becomes too great, the diaphragm is raised, and the contact is made, which switches over this rocking switch, and the cells then being considered to be thoroughly charged, are transferred from the charging system of mains to the service system of mains. That is the arrangement which was adopted there. One of these cells which are used there is shown here, one of the Consolidated company's cells, which I have lately had the opportunity of testing very carefully, and which seems to give fair results; and I have upon the table below two plates, a positive and a negative plate, and you can examine them and see how they are constructed. Let

Digitized by Google

me put in a word here in parenthesis. I do hope that those who are electricians will not allow the term negative to be applied to what ought to be positive, and the term positive to what ought to be negative. I cannot understand why, since secondary batteries have been introduced, the whole language which electricians have been accustomed and got habituated to should be utterly reversed, and if certain companies, who make these batteries persist in calling the plates in that way, I dont see why electricians should adopt them, and why they should not stick to the terms they have been accustomed to use. I only hope a word put in in season here and there will lead to electricians insisting on proper terms being given to these plates. Here also I have some plates well worthy of examination, kindly lent me by the Electrical Power Storage Co. I may say that I had the good fortune to look through the work they have been doing of late, and I have been very much struck by the enormous progress they seem to have made in the practice of the construction of cells and the maintenance of them in good order and the prevention of the sulphating of these plates, which has been a source of very great trouble; and one of the chief things I was shown was the way in which these negative plates are kept in good condition, and how it is impossible to injure them, apparently, by over-charging. I believe I am right in pointing to this one (indicating a cell on the table) as one which has been persistently over-charged with the idea of trying to damage it, trying to make it worse, and if you look at it you will see as good a plate as you ever saw in your life in any secondary battery, the material perfectly sound and excellent. It really seems to show that one of the chief difficulties that has been met with is charging with too weak a current, and allowing the battery to degenerate, and not keeping it thoroughly charged up.

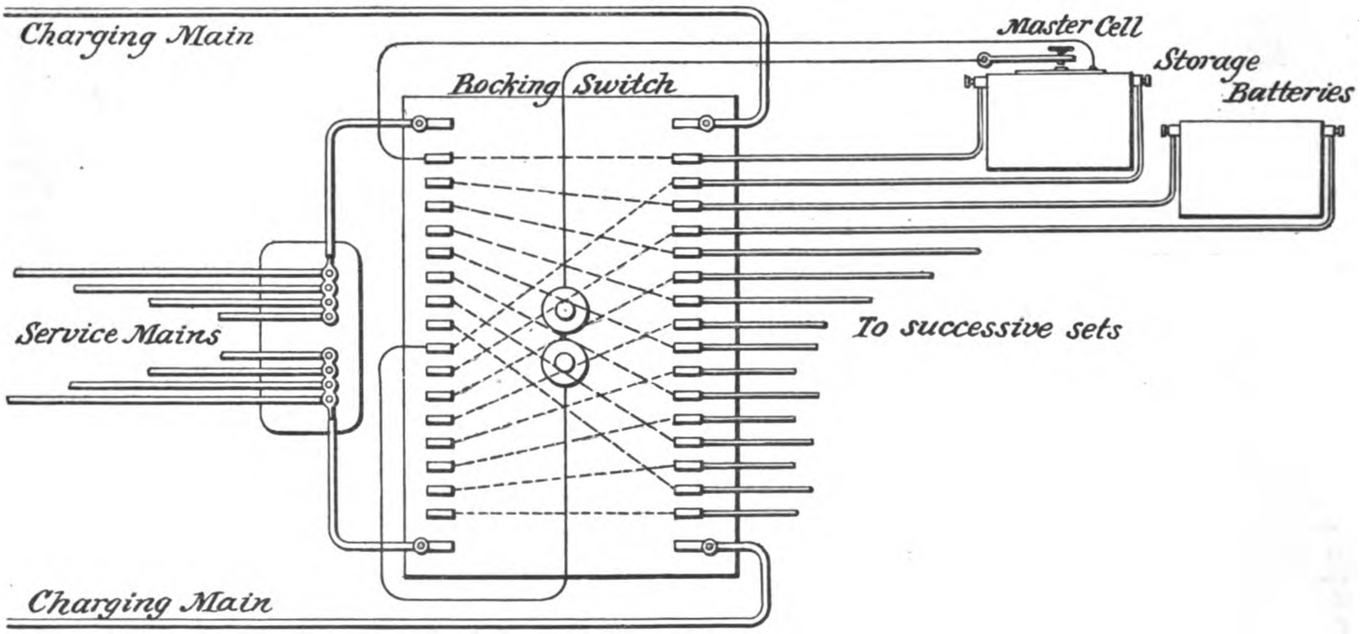

FIGURE 2.

SECONDARY INDUCTION CURRENTS.

Next, I wish to draw your attention to a system of supply with high potentials which has been introduced by means of secondary induction currents. It is a very old idea, indeed, to use induction currents in order to use a high potential current in the mains, and a low potential current in the supply service. I believe that the first patent which I have come across which was taken out in connection with this was by Mr. Harrison, in the year 1857, and since then it has been patented over and over again, and here is a general idea of it shown in this diagram, fig. 3, where there are supposed to be rods of iron (indicating) surrounded by coils of the main wire; here is the main wire coiling around one end of these iron bars. The lamps, then, are connected, their terminals, by a wire which coils around the iron bar also, an alternate current is used to pass through these main coils, and it sets up alternate magnetization in opposite directions by these iron bars, and the magnetization induces electric currents in this wire which is connected with the lamp, and consequently we are able to magnetize this bar by the main wires with any potential that we please, and we are able to draw off by these induced currents a current of any potential that we please. In this way different lamps in different parts of the circuit can be fed with a current of whatever pressure you please, although the main exciting current is of very high pressure, indeed; but, mark this, there is absolutely no danger in this system, because the charging current is in a closed circuit which never goes near the rooms where the lamps are actually at work; a lamp thus never has over the potential which is required for that lamp, and the high pressures which are used in the mains are confined simply to a closed circuit of wire; therefore there is absolutely no danger in such a system. I have said that this is a very old system. The idea is very old; but it is only in the last few years that it has been worked out practically and with confidence, with a confidence that does honor to M. Gaulard, I may say, for the way in which he has attacked the problem; he was confident from the very first. I think it was three or four years ago when we first saw his apparatus in the Westminster Aquarium; since then he has been improving it, and has brought it to a practical issue. Since then I have not myself had the opportunity of experimenting upon those apparatus; but I simply draw my conclusions from the reports, in the first place, made by Dr. Hopkinson and others; and I have not the slightest doubt that from these secondary generators it is possible to get a return of 90 per cent. in the lamp circuits. This is a result which is very remarkable, and is worthy of far more serious consideration than it has received up to the present time from most people, though, of course, many advanced electricians have been looking with eager interest at the result of these experiments. During the course of the last summer experiments were being made, as most of you are aware, at the electrical exhibition at Turin, and I have here a plan of the scheme which was used there, and of the way in which the wires were

Digitized by Google

used. Altogether the circuit had a length of about 50 miles; and we have evidence of the large number of different kinds of lamps used upon that circuit—a large number of Bernstein, Swan, Siemens, and Edison lamps—a large number of different lamps of different pressures, all worked from that central station over that great distance, so that the matter of distance is apparently overcome; these distances were, of course, much greater than they would be in any town distribution. I don't think I will say anything more about the system just now, except this: that if there is no difficulty about the expense of it, it is well worthy of far more attention than has been given to it up to the present. I had the pleasure of looking at the installation which is being commenced at the Grosvenor gallery the other day, and I see there is no doubt we shall have an opportunity very soon of seeing a very large installation there, and at the Inventions exhibition there is going to be a considerable amount of work done by the same system. After those two experiments we shall be in a position to judge whether, economically, it is good. In every other point, except, perhaps, the induced currents which the alternate current machines may create in telegraph wires and other circuits, there really seems to be no objection to the system. It is true there is a great objection to alternate current machines, but when we come to examine it there is very little to be argued against it; if the leading and return wires are brought very close to-

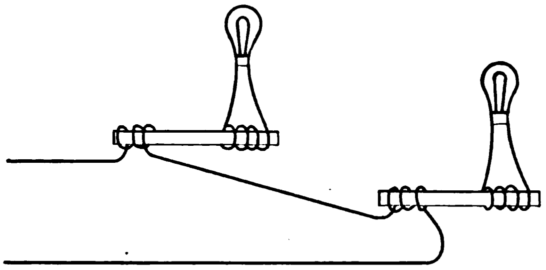

FIGURE 3.

gether, induction in neighboring telegraph wires is small, and I really think that we ought to look—all electrical engineers ought to look—very closely into these experiments which are being made just now, for it really promises well.

THE MULTIPLE SERIES SYSTEM.

Now let us go on to the other systems, and which are more analogous to those which we have been describing previously; and, first, let us speak of the multiple series system. Here is a system, which I have alluded to, of multiple series on which there are two lamps on every series, fig. 1. Now the trouble of that was, when it was first introduced, that if one of those lamps went out, the other in the series went out. In order to prevent that, it was suggested to bring a wire connecting the intermediate position to all the lamps in the circuit. Then if one goes out, the other does not, because it is fed by the current coming from the other lamps. Another example shows it in a different manner. There we go through successive pairs of lamps, the pressure gradually falling as we go along, and pass through the nine different series connected up. I do not know when this system was first proposed; it is very old, I believe. The first time that it was practically seen in action was, I believe, at the Paris exhibition of 1881, when Mr. Edmunds lighted the Congress Salon by Swan lamps, the lamps all being fitted in multiple series in this manner. After that the most important experiments made were those by Mr. Preece at Wimbledon last year, when, in some experiments he made for the commissioners of sewers, he lighted up a large part of Wimbledon with incandescent lamps, all on the multiple series system; and quite lately we have had brought before our notice by Mr. Kierzkowski-Steuart an admirable account of the lighting of Temesvar, in Hungary, by means of a multiple series system like this, in a very remarkable article which appeared in a recent number of *Engineering*, giving a detailed description of the arrangements there, which had, undoubtedly, been worked out with very great care before laying down the installation. Now, the multiple series system is one which is admirably adapted to certain cases; it is admirably adapted to Temesvar, in Hungary, because it is only used there for street lighting, and the lights are always all required at the same time. But it is not suitable for house-to-house distribution, simply for the reason that, if some of the lamps are put out, then the other lamps on the circuit have too much current. Having shown by experiment how this would act, the lecturer proceeded: Now that would be intolerable in a general supply of electricity; that when one house in a block of buildings was using rather less current than usual, other persons in that block should get far too much current, would be intolerable, and that the next block of houses should receive so little current as was shown by these lamps (in the experiment) would also be intolerable. Various devices have been proposed for getting over these difficulties. I will deal with one or two. The first system which I shall speak of is one which has already been put into practice, and it is undoubtedly a most ingenious principle. That is what is called the three-wire system, which Dr. Hopkinson originated. (See page 102, March, 1885, ELECTRICIAN AND ELECTRICAL ENGINEER.) There we have two dynamos at the central station working in series, working through each other; that is to say, in the hydraulic analogy two pumps working in series so as to send the water from the pumps at a very high pressure, if such a thing could be introduced into hydraulic engineering. The supply mains come from the extremities of two wires, but there is a third supply main which comes from the intermediate point and connected between the two dynamos, and the lamps are attached to branches which may come from the first main to the intermediate, or, as it has been called, the compensating main, and some of the lamps are attached to branches which are connected with the last main and the compensating main in the middle. By this means we are able to use twice the E. M. F., twice the pressure, by using the dynamos in this way. Of course a great difficulty, as I have mentioned, would occur, were it not for this central connection of the compensating wire; if there are more lamps in use in the first series than in the second series, then it would be necessary to drive the first dynamo so as to give a greater current than the second dynamo is giving, and then, by adjusting the pressure of the two dynamos, we are able to give a constant supply to both sets of lamps, and at the same time to work them in series. This line here is supposed to represent a point of very large consumption, such as a theatre, when the wires come some from the first main and compensating conductor, and some from the second main and the compensating conductor, but in about an equal number, so that if the theatre is put out of a sudden the disturbance in one series of mains will be the same as in the other, and there will not be that change in the light shown you just now.

ECONOMY OF THE MULTIPLE SERIES SYSTEM.

Now as to the economy of this system. In the first place, you will notice that, as I have arranged it here, which is the manner in which Edison has used it, the fall of potential is at the same rate as it is with the ordinary multiple arc distribution; therefore, according to this way, in which lamps are led off from two pairs of mains at every part, the distance to which these mains can extend is still limited, as it was in the multiple arc system, to 124 yards. But it would be equally possible to use only the first main and the compensating main up to a distance of 124 yards, and then to use the compensating main and the second, the lower potential main for another 124 yards. Now as to

Digitized by Google

the economy. A great deal of exaggeration has been introduced in America into the accounts of economy in this system. It has been said that, since you are using only half the current when you double the number of dynamos, therefore you have half the size of mains; but then you have three mains instead of four; therefore, they say, you have a gain of 25 per cent. for that reason; but then, they also say, you have got twice the pressure you had before, and again you may halve your mains, and, altogether, they tell you, you can make a saving of copper of 62½ per cent. Now, this may suit American financiers, but it is not electrical engineering. As a matter of fact, in the two cases, in the place of having one dynamo and one pair of mains, I introduce two dynamos and three mains. I have half the current passing through that wire, and, therefore, I may have half the diameter of it, but there is no further reduction possible. I assume that I may take it for granted that the axiom which we worked out in the first lecture must be accepted as an axiom in all future time; that is, that to get economy in our mains we must use the most economical size of conductor possible. In that case, the size of conductor is simply proportionate to the current it has to carry; therefore, the total amount of copper you have to lay down is simply three-fourths of the mass of copper which would be laid down in an ordinary multiple arc system. At a meeting of gentlemen interested in electricity lately, this subject was broached, and I ventured to mention this point, then simply because the originator was present, and I may say that Dr. Hopkinson thoroughly coincided with me in the views I have given you, so that it is evidently purely an American idea.

If we increase the number of wires from three to a larger number, then we increase the economy, but if all the wires are of the same size, then the limit of economy, the maximum of economy would be to reduce the copper by one-half; but it is possible to reduce the compensating wire to one-half, and I should think it might be reduced to one-half, and in that case the limit will be one-fourth; that is to say, when you put a large number of series, you will have about one-fourth of the copper which you have otherwise in a multiple arc system. However, if we wanted to be absolutely certain that our lamps would be in perfect working order, and that our conductors would be of suitable size, perhaps it would be right that all these three conductors should be of the same size, because such a consumption might arise. I am not of this opinion, but suppose we say that, then would come the question whether it is not possible to devise some other means of reducing the thickness of these intermediate wires, these compensating wires. And this is what Mr. Edison has accomplished, on paper at least. In a very interesting patent which he took out in 1883, he has described a means of switching over the lamps from one pair of mains to the other. Now I believe there is a great deal in this, and I believe it is possible in this way to make the householders themselves regulate their supply to a great extent. Just think what you do with your own gas; when you first light your gas, if your burners are as bad as burners usually are, your light flares, and you have to turn it down; after a time, when everybody else is using the gas, you have to turn it up again; then, late at night, when everybody has gone to bed, and you are hard at work, you require again to lower it. If every householder had a switch so that he could switch his own lamps on to one pair of mains or the other, when he found his light dull he would fiddle away with his switch, and in that case he would not only make his own light better, but everybody else's, and every person in the district would be helping the others to acquire the right potential. No knowledge of electricity is required; no householder has to know what he is doing; he has simply to follow the natural instinct which a householder has of fiddling with his gas jet until he gets it the best way possible, and thus it is just possible that to some extent that may be of use. Mr. Edison proposed to use this system of switches, with the three-wire system in combination with it, so that he will not get a perfect compensation by either the one or the other; by the combination of the two he will get a perfect system and a perfect compensation. He has also proposed, in the same patent, to introduce automatic switches, switches which may be influenced by the pressure of these mains locally, or switches which may be influenced by the person in charge at the engine house, so that wherever there is a deficiency of potential lamps may be switched over. It is very probable that some development on this line may lead to important results. I have myself tried to extend the system a little, not in connection with the three-wire system, but in connection with the simple two-wire system.

Now what is necessary in order that we may have equality of current in different sections of these series? It is necessary that we should be able to switch over one or more lamps, or one or more houses supplied with lamps from one to the other. Now what I should propose in this system would be the switching of the mains over. In this case the main, which is connected to each house, is broken between each pair of houses, and I can connect them simply by putting the second main there to the left, the fourth to the left, the sixth one to the left, and so on, and doing the same with the negative main, I should get exactly the same distribution, and I could vary with such a system as this the number of series that there were; I could connect half a dozen of these branches of mains together, and then 12 of these below, and then go on in the same way, from step to step, and introduce only two or three series in the whole of this circuit, or I might introduce as many as 20 or 30, just as I pleased. If one had a very long circuit over a lamp district, one might arrange them in any number of series one pleased, and one could switch over a house from one main to a main of higher pressure, or from a main of high pressure to a main of lower pressure.

CONCLUDING REMARKS.

Now the time has come when we must conclude this course of lectures; and, in conclusion, I have only to say that I think you will all agree with me that, when we attack the problem of electrical distribution in a serious vein, we find that it is rather simpler than it seems at the first blush. It has been well said by one of our most distinguished electricians that in the past the distribution of electricity has been the *crux* of electric lighting; it has been there that the difficulty has been. Undoubtedly the electric lighting act has done an enormous deal to hinder electric lighting, but every electrician must admit that there has been a difficulty in the question of distribution; and I think you will all agree that the further we go into it, the simpler are the rules which guide us, and it is only that schemes have generally been commenced in a slightly haphazard fashion that difficulties of a serious character have seemed to present themselves. In every special district the engineer must use his discretion as to the kind of distribution which he is going to employ. But even in large districts, I think you will all agree that the consideration we have given to it shows that it is a possibility to lay mains on economical principles which shall suffice for lighting large districts, if no undue hindrance is put in the way of enterprising undertakers by the authorities that are in power. The past history of electric lighting has chiefly dealt with the system which I first spoke of in my last lecture, the multiple arc system, but I do not hesitate to say that the future of electric lighting, on a large scale, will deal almost entirely with the systems which have been touched upon to-day. And especially I would draw attention to these different schemes and their value for the reason which I have already mentioned, that in the future we may have inventions in secondary batteries, or we may have other inventions, but whatever invention there is favoring electric lighting, it will be of a nature suitable

Digitized by Google

for using the thinner conductors, which we would naturally lay down with any high potential system which I have spoken of this evening. Therefore, the engineer, in designing a system of mains, would have a natural bias towards such thin conductors, such high potential mains; for that reason he would advise it, as well as for other reasons. When we are able to use, as I confidently believe we shall, a pressure of 5,000 volts, we can diminish the thickness of our conductors to one-fiftieth part, and for a district of 50,000 lights we should only require a conductor of about an inch section of copper. When we are leaving the idea of masses of copper of the size of a man's body, and coming down to masses of copper an inch or even two inches in diameter, I think we are really coming to the question of practical electric lighting. And all this has been done—is not merely theoretical; it has been done to a considerable extent already, and that is the direction in which progress is being made at the present time.

I can only say that I hope the Parliamentary difficulties which have partly stood in the way of electric lighting in the past will soon be entirely removed, and that others will prosecute the question of electric distribution, so that we may be all thoroughly ready for it when we have greater facilities for electric lighting in the future, because there is not the slightest doubt that the question of distribution had not been sufficiently developed when the electric lighting act was passed, and if we are ready in the future when those great concessions which must be granted by this or a succeeding government—because it is simple justice—when those concessions have been granted, let us trust that engineers will be perfectly ready and be able to supply a scheme which is perfectly satisfactory. (Applause.)

Mr. Preece, in proposing a vote of thanks to Professor Forbes, took the opportunity of indorsing what the lecturer had said with reference to the danger of high potentials. He was quite sure that electricians were far more able to protect the public from even 50,000 volts than gas engineers were to protect the public from explosions, or ordinary steam engineers from bursting boilers.

Professor Forbes suitably acknowledged the vote of thanks.

THE CONSTRUCTION OF LINES FOR ELECTRIC CIRCUITS.

BY THOMAS D. LOCKWOOD.

(Continued from page 208.)

In jointing copper lines, if soft copper is used, the ordinary twist joint as already described may be employed. For hard-drawn copper wire such as that employed in telephone, trunk, or in telegraph lines, it does not answer, as it is apt to break the wire. Two other methods present themselves ; one of which like the twist joint requires no other material than wire in its formation ; the other requiring a socket or casing. The first mentioned is the Britannia joint. After many trials of other devices this has been almost exclusively adopted on the British telegraph lines, and when well made it is a wonderfully effective splice. A view of it is given in figure 14. In making it, the ends of the wire are to be scraped clean and bright for about two inches ; they are then laid side by side as shown in the figure, and held tightly together while they are carefully bound over with No. 16 wire of the same material.

In jointing copper wire, the binding wire must be a little softer than the line wire. When this is done the whole is well soldered and makes a homogeneous, and first-class splice. Some copper wires which were so jointed under the supervision of the writer, were afterwards tested by a hydraulic machine, and the wire parted, in preference to pulling out the joint in all cases. It should be here noted that in soldering the Britannia joint in copper, the solder should only cover the middle portion of the joint, as if used over the whole of it, the wire near the end of the splice becomes brittle.

The turned up ends should finally be cut off close, to prevent them from hooking parallel wires when blown about by the wind and causing crosses.

The remaining plan which may be adopted is to place the two ends (cleaned of course) in a metal socket or

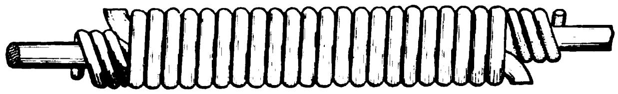

FIGURE 14.

sleeve, such as indicated in figure 15, and then to fill the interstices, and surround the whole with solder. Several patents have been taken out for such devices. One of the earliest is as good as any. It is that of Cary, patented June 20th, 1871.

The sleeve (which should be of the same metal as the line-wire) is enlarged internally about the middle, and has a hole through the centre from side to side. The wires are brightened and the two ends are inserted in the sleeve, one in one end and the other in the other end, so as to meet and overlap one another. A steel punch is then driven through the hole in the side of the sleeve, which forces both wires sideways into the enlarged chamber at the middle, leaving a space between them in which a rivet is passed which is hammered down.

The joint after being soldered over is complete. No joint of this class having projecting screws or lugs is admissable, as such excrescences are quite apt to hook to other wires. For the same reason no joints or splices ought to be made more than 12 feet from a pole ; when at a greater distance they are likely to hitch to other wires; and if it is ascertained before stringing the wire that a joint will have to be made in the middle of the span, it is better to shorten up the end so as to bring the joint nearer the pole.

A small soldering stove should be carried along, so that a supply of melted solder may be at all times ready. It is not a good practice to pour the solder over the joint ; a better way is to dip the centre of the joint entirely into the melted mass. The best solution as a flux for soldering iron wire is chloride of zinc, made by dropping a few small scraps of zinc in hydrochloric acid. The solder makes a solid metallic mass of the joint, which is then as sound and durable as any other part of the line-wire. Any excess of the acid must be wiped off so as to prevent it from acting on the wire. In soldering copper wire, chloride of zinc

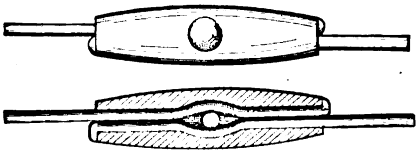

FIGURE 15.

should not be used ; neither should it be used in joints between iron and copper wires. Rosin is the only safe flux to use for such work. Hard wire must be soldered at as low a heat as possible, so as not to soften the metal and weaken it.

TERMINATING WIRES.

The usual way to terminate a wire is to wind it once round the insulator, and then bringing the end back parallel with the wire to give some half dozen or more turns round it.

This can readily be done as in figure 16, with iron wire not over No. 9 in size, or with soft copper wire ; but with

Digitized by Google

hard, copper wire, or very large iron, the better way is to terminate the line in the way shown in figure 17, by wrapping the line once round the insulator, or knob, bending it up to shape, and then binding it round with wire not over

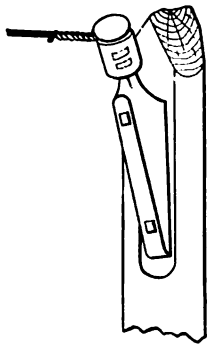

FIGURE 16.

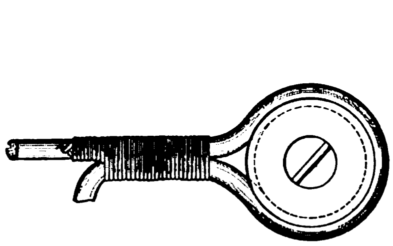

FIGURE 17.

No. 16 in size. The binding wire in such a case as this, need not be soldered as it is not a connection affecting the continuity of the line.

RUNNING HOUSETOP WIRES.

Many of the remarks already penned are applicable alike to pole and housetop lines—and there is very little to add which is specially pertinent to over-house construction. There is much more guying however to do. The slightest turn or angle should be guyed. Nothing but the very best extra B. B. wire should be used, if iron wire is employed; and wherever cables can be introduced, on a line where there is a multiplicity of wires, it is a good thing to use them, as there is no neater way of carrying a number of wires from point to point. Wherever possible wires should cross streets at right angles, as by so doing the risk of accident by breakage is much diminished. A most important point in housetop work is one which is quite frequently neglected—*i. e.*, to keep the roofs quite clear of odds and ends of wire and other debris which rusting, accelerates the oxidation and wearing out of the roof.

ELECTRIC LIGHT WIRES ON TELEGRAPH AND TELEPHONE LINE SUPPORTS.

It has been a question which has been freely discussed, whether in case electric light wires are suspended upon electric communication supports, they should be placed above or below the other wires.

With telegraph lines the only danger if the lines are well insulated is that of actual contact, which can be reduced to a minimum by good work. But with telephone lines the case is different. Not only by actual contact, but also by induction do the voluminous currents of the electric light affect the extraordinarily sensitive instruments which reproduce vocal utterances.

It is therefore not wise to permit light wires on telephone supports at all, unless they are better insulated than they usually are, and unless they are run as metallic circuits with both wires near together on the same support. Viewing the case in all its aspects, it seems best if the different systems *are* to be run together, to place the wires of the lighting system on the top, and to make an unusually high structure for that purpose. It ought also to be put up in an extra strong manner so as to stand an abnormal strain. When a wire carrying a heavy current is so placed it involves two solid advantages which are:—first, that linemen going up the pole or fixture to examine or repair other wires do not have to jeopardize life or limb by passing over a dangerous wire every time; and second, that should the wire carrying the lighting current break down, it is but one wire to fall over the top wires of the systems below, while if it should be placed below everything, scarcely a wire could break and fall, without passing over and contacting with the line-wire.

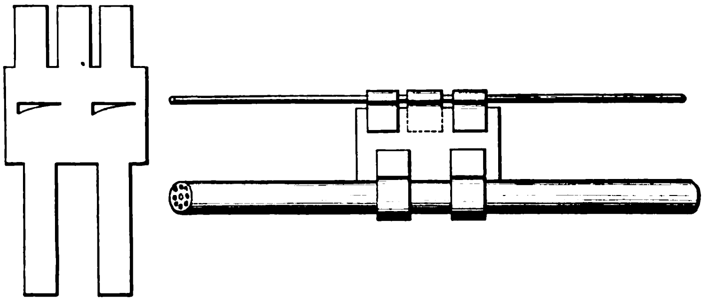
CABLE SUPPORTS.

Various styles of suspension wires, or as they are wrongly called by telephone linemen "guys," are used, and many different ways of hanging the cable to them are adopted.

The suspending wire should be of steel or the best iron wire, No. 4 to No. 6 in size according to the size and weight of the cable. No. 4, I think, is to be preferred; the supports must be strong, and the wire well anchored at both ends, and securely fixed wherever opportunity is afforded. A strand composed of seven or eight No. 13 or 14 wires, or of three or four No. 6 iron wires is better in every respect than a single wire, and is more reliable. It should be guyed to balance lateral strain, and to maintain rigidity, but should not be stretched tight; for the reasons which I have already set forth. In the matter of suspending devices, nearly every one concerned in the erection of aerial cables has his pet clip or attachment.

In New York a favorite method has been to clasp the cable and suspending wire with a reel of marlin or tarred yarn or cord, and then drawing the reel forward, the cord (previously fastened by one end at the starting point) is caused to surround both suspending wire and cable in long spirals. This method was invented and first applied by Mr. C. E. Chinnock.

In some cities the cable is suspended simply by double hooks of the well-known pothook form, endeared to us by childish association with our first essays in the art of caligraphy. These hooks are made from line wire varying in size from No. 10 to No. 8. Sometimes again slings of tarred canvas are used, but these can hardly be considered durable.



FIGURES 18 AND 19.

Another form of hanger was devised by Messrs. Eckert and Seely, now of the Metropolitan Telephone and Telegraph Co., New York. It is made of sheet or galvanized iron. The blanks are cut out of the iron; and the upper edge is cut into three arms with spaces between them, which arms are lapped over the suspending wire. Figure 18 shows the blank as it is cut, and figure 19 the appearance of the clip when made up and attached.

Two horizontal slits are cut in the central portion of the iron, and the lower edge is cut into two long fingers, which when bent over, can be thrust through the horizontal slits, and a socket is thus formed in which the cable lies.

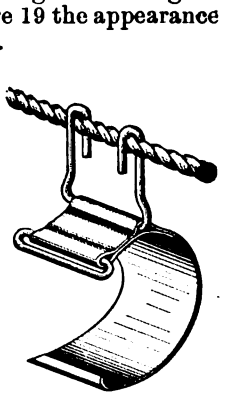


FIGURE 20.

Another good clip is that of Mr. Wright, of Providence. It is illustrated in figure 20. Description is scarcely necessary since the cut is quite clear and speaks for itself. It is made of very strong sheet metal, and when the cable is inserted the free end is hooked up into the link provided for it where the strain holds it securely. As shown it is provided with a double hook, and one size of clip will fit several sizes of cable.

THE FREEMAN TELEPHONE PATENTS.

On the 19th of May, 1885, two patents were issued to James P. Freeman, of Chicago, Ill., for improvement in methods and apparatus for telephone transmission, which have apparently excited an unusual amount of interest in electrical circles, if we may judge from the number of newspaper paragraphs which have been sent us, and the considerable number of inquiries we have received as to the character of the invention. A critical examination of these patents shows conclusively that the real object of the patentees was to obtain from the United States Patent Office a *prima facie* endorsement of the claim of the inventor to the possession of a telephonic transmitter, which operates by make-and-break, or interruption of the current, and hence professedly upon a method which differs essentially from that of the Bell patent, and accordingly does not infringe it.

The construction and mode of operation of the apparatus will be readily understood by the aid of a brief explanation in connection with the accompanying drawings, in which figure 1 is a view in elevation of the transmitter box with its door open to show the interior parts, and figure 2 is a detached view showing the manner in which the electrodes are mounted.

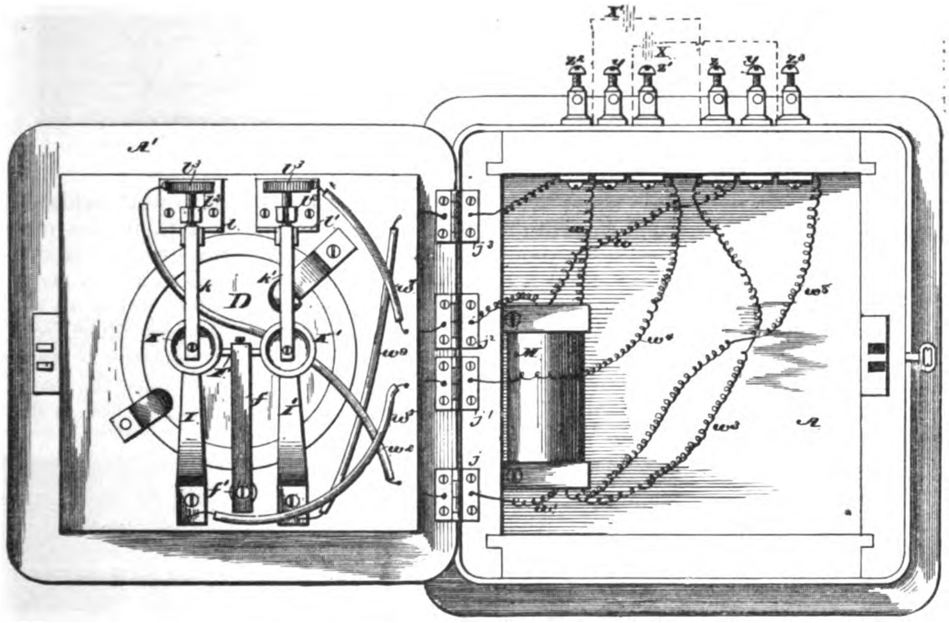

Figure 1.

This instrument in its organization is to all intents and purposes, a double-barreled Blake transmitter, that is to say, it has two sets of Blake contacts thrown into vibration by one diaphragm. The contacts consist of a metal electrode, *h*, and a hard carbon electrode, K. Each metal electrode, *h*, is carried on the end of a long slender spring, I, which tends to press it towards the carbon electrode, K, and each carbon electrode is carried on the end of another long slender spring, *k*, to which an adjusting screw, l_3, is applied so that the latter can be pressed towards the metal electrode. The carbon electrode is mounted in a brass thimble, and is like the Blake electrode, especially in respect to being heavy enough to possess the requisite inertia. The diaphragm, D, through an intermediate pin presses on the bar, F, that carries the two metal electrodes, in such a way that the vibrations of the diaphragm tend to move these metal electrodes towards or away from the weighted carbon electrodes. An independent local battery circuit is provided for each set of electrodes. So far the instrument is nothing more than two sets of Blake contacts connected with one diaphragm, and when spoken to the inevitable result is to produce the precisely same kind of an "undulatory current" that the Blake instrument does, and to do it by the same mechanical means, viz.: the combination of carbon and metal electrodes, each carried on the end of long springs, one vibrated by the diaphragm, and the other provided with a weight at the end of the spring. These two metal electrodes are mechanically (though not electrically) connected with a bar, F, which is pivoted near its middle like a lever. It is easy, by means of the adjusting screws, l_3 l_3, with which the instrument is provided, to keep both of the contacts permanently closed, and in such case the instrument operates precisely the same as two Blake transmitters mounted on the same diaphragm. There would obviously be no difficulty in adjusting them, so that they would slightly rock on the axis, *c*, and break contact alternately, each closing its contact at the same instant the other broke. In this case there would be a continual contact somewhere, although it would be first on one electrode and then on the other, a somewhat similar effect to that which is obtained in another well-known instrument.

The inventor alleges that he turns the adjusting screws so that one contact shall break an instant before the other closes, and that there consequently is an instant when there is absolutely no contact, but inasmuch as all the contact parts are mounted on the ends of long springs, it is wholly improbable that this takes place in any ordinary use of the instrument. The inventor, however, says that even if it does take place, the period of break is so short and so slight that it does not practically interfere with the transmission of speech. No one familiar with the operation of the telephone will believe that *any* breaks occur when it is transmitting good speech; but if the statement in the specification be correct, then the construction of the instrument, as well as the inventor's own description of its method of operation, shows that each contact, during nearly all the time, is simply engaged in producing an undulatory current, precisely like that of the Blake, upon which is superposed a greater or less number of breaks so short as not to prevent speech from being understood. The statement in the specification is that "while it is true that there is an instant of time between the breaking of one primary circuit and the making of the other, and *vice versa*, the making and breaking of such circuits are so rapid that every word and every part of every word spoken in front of the instrument is taken up and transmitted clearly and distinctly. This result is due to the peculiar construction of the instruments embodying the invention in each of the forms shown."

The two pairs of contacts are included in independent primary circuits, but those circuits go through two primary helices connected with the same induction coil, which is furnished with only one secondary, so that their effect is at least as good as if they were arranged in the same primary circuit. The inventor also winds the two primaries in what may be termed reverse directions, or, in his own words, "such that the breaking of one induces a current in the same direction as it does in the closing of the other." It may be remarked that this tends to compensate for any disturbance which might otherwise be produced by the imperfect mechanical action of the rocking lever, the effect of the rocking on one pair of electrodes being compensated by its reverse effect upon the other.

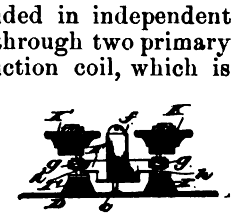

Figure 2.

Digitized by Google

The whole apparatus is nothing more than a repetition of the attempt which has been so frequently made, to arrange an instrument which can be called a "circuit-breaker," because the parts are capable of being so adjusted as to be out of contact, but which, nevertheless, is provided with all the necessary operative contacts, so mounted on the extremities of long and weighted springs that when the instrument is spoken to, they are normally and habitually in contact, and produce the ordinary undulatory current, in spite of occasional interruptions by breaks too slight, or, as the patent says, "too rapid," to prevent speech from being understood.

The descriptive portion of the specification is substantially the same in the two patents. No. 318,424, which relates to the specific construction of the apparatus, does not call for special comment. No. 318,424 has the following claims:

> 1. The method of transmitting articulate speech telephonically, which consists, first, in causing primary intermittent electrical impulses in the transmitting circuits through the agency of sound-waves due to articulate speech; secondly, causing said primary impulses to generate secondary electrical impulses of an alternating nature; thirdly, causing said secondary electrical impulses to actuate a receiving telephone at a distant station, and reproduce said articulate speech accurately and clearly, substantially as described.
>
> 2. The method of transmitting articulate speech telephonically by causing intermittent electrical impulses to traverse an electrical circuit, and thereby generate secondary electrical impulses, which secondary electrical impulses in turn actuate a telephone receiver, and cause it to accurately reproduce the aforesaid articulate speech, substantially as described.

It will be noticed that these claims, especially the second, are modeled upon the fifth claim of the Bell patent, and that the method claimed is nothing less than the telephonic transmission of articulate speech by intermittent electric impulses.

From the description which we have given of the mode of operation of the apparatus, nothing can be more certain than that the transmission of speech by it is in fact effected *in spite* of the intermissions in the current, and not *by reason* of them. This is a very important distinction, but is one which has already received such thorough discussion in the technical journals that it seems hardly worth while for us to add anything to it. Nevertheless, it would be interesting to know by what means the Patent Office was induced to grant a broad claim for a method of transmitting articulate speech by intermittent impulses, based upon a specification which really describes nothing of the kind, but, on the contrary, a transmitter operating to produce undulatory impulses precisely like the Blake transmitter. The fact that the late Commissioner of Patents, E. M. Marble, appears as the attorney of the inventor, and also as the assignee of nine-twentieths of the patents, is perhaps sufficient to indicate the nature of the influences which were probably brought to bear to secure the allowance of this extraordinary claim. The careful observer cannot fail to be impressed with the peculiarly funny circumstance, that the inventor of this telephone should have adopted the precise mechanical arrangement which was found by such a careful experimenter as Blake to be adapted to secure the widest range of variation of pressure without interruption, and applied it unaltered to the purpose, as he asserts, of producing very minute and carefully regulated breaks, requiring the most accurate micrometrical adjustment.

Without expressing an opinion as to the value of this invention from a practical point of view, we may say that there can at least be no doubt that the patents are admirably adapted to form the basis for a heavily capitalized stock company, in order that its philanthropic promoters may make one more attempt to rescue their oppressed fellow citizens from the relentless grasp of the alleged "telephone monopoly."

ON CHARGING SECONDARY BATTERIES.[1]

BY WILLIAM HENRY PREECE, F. R. S.

1. I have for some months past been experimenting with secondary batteries with a view of getting an efficient, uniform, and constant source of currents for electric lighting my house, and I have succeeded beyond my expectations. Some new facts have developed themselves during my experience, which I have thought of sufficient importance to bring before the Society.

2. The cells are of the Planté type, manufactured by the Elwell Parker Co. of Wolverhampton. Fourteen plates of

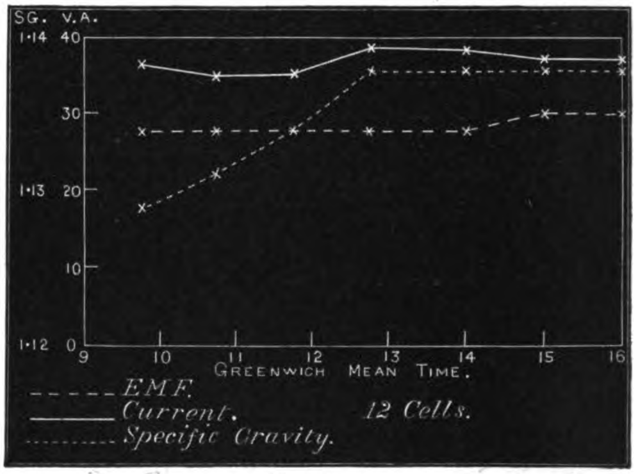

FIGURE 1.

plain sheet lead 17″ × 11″ are suspended in well insulated wood boxes filled with diluted sulphuric acid in the proportion of about 1 to 10. These plates are grouped in two groups of seven, each group being soldered to a lead strip, forming alternately the positive and negative poles of the cell. The plates of the respective poles are prevented from touching each other by ebonite grids or separators.[2] Each plate offers a surface of 1·3 square feet, so that the total surface of lead of each group opposed to each other is 9·1

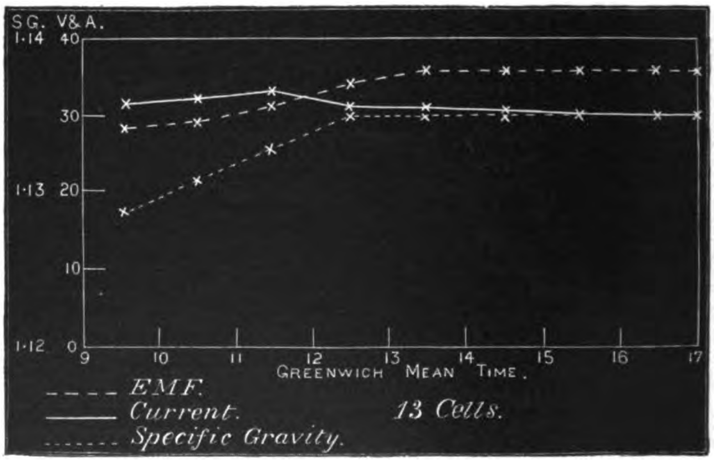

FIGURE 2.

square feet; that is 9·1 square feet of peroxidized lead is opposed to 9·1 square feet of spongy lead.

3. My charging current varies from 3 to 3½ ampères per square foot, while the current of discharge used in lighting my house varies from 1 to 1½ ampères per square foot. The total weight of each cell is 120 lbs. The plates are prepared by the Parker-Planté process before insertion in the

1. Read before the Royal Society, May 21, 1885.
2. These ebonite grids were introduced by Mr. Charles Moseley, and have effectually removed one incessant source of trouble in these cells, viz., short-circuiting through the buckling of the plates.

Digitized by Google

cell, those forming the positive pole being well peroxidized, while those forming the negative pole are well coated with spongy lead.[3] They are thus, when put together, prepared at once to be charged. If they are not at once charged, local action sets in, and lead sulphate is injuriously formed.

4. I have cut away a small portion of the centre of the central plate of each cell to admit a hydrometer, having a scale graduated from 1·050 to 1·150 (Frankland, "Proc. Roy. Soc.," No. 224, 1883). The changes of the density of the liquid and of the color of the plates give the fullest and clearest indications of the behavior of the cell. The condition of the surface of the peroxidized plate as felt by the finger is also good evidence of its condition. If a plate is yellowish-brown and rough, it probably makes bad contact with the lead terminal; if black and hard, it wants the density of current regulated; if plum-colored and greasy to the touch, it is in good order, and working well. Now that my plates have been in use for some time they seem far less inclined to local action. In the oldest cells no local action is evident.

5. At the present time I am charging my cells twice a week, putting in at each charge about 120 ampère-hours. During charge observations are made every hour, and sometimes every half-hour,—(1) of the strength of current flowing through; (2) of the electromotive force; and (3) of the density of the liquid of one or more of the cells. The relation of these three quantities tells me the condition of the charge. The diagrams herewith are typical cases :—

Take No. 4, which is the diagram of this morning's (April 28) charge of 15 cells. The following are the particulars :—

	E.	C.	D.
9.0 A. M.	37·7	32·24	1·115
10.0 "	40·2	32·24	1·119
11.0 "	42·5	31·50	1·121
12.0 noon	42·5	30·74	1·123
1.0 P. M.	42·5	29·95	1·124
2.0 "	42·5	29·95	1·124

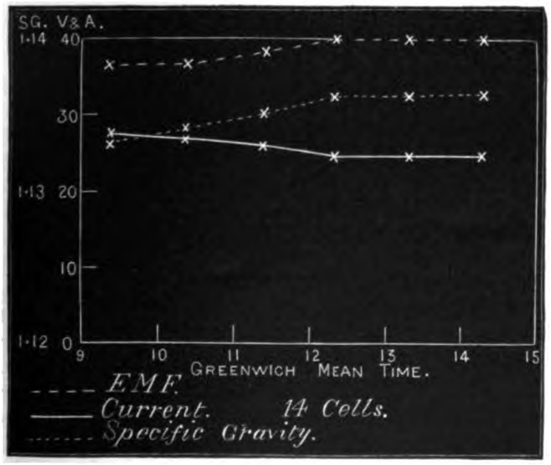

FIGURE 3.

6. It is evident that after four hours continuous charging the battery was full, for the density, the electromotive force, and the strength of current became constant. The same scale of ordinates is used for volts and ampères. When each magnitude reaches its constant, bubbles of gas are freely given forth, and energy is being wasted. The variation of the electromotive force and current strength is clearly due to the counter-electromotive force of the cells, which becomes a maximum only when the plates are fully formed. The counter-electromotive force partakes of the character of a higher resistance opposing the charging current, and increasing the proportion of the current through the shunt of the dynamo. Hence the changes of electromotive force are more marked than those of the current. Indeed, the changes in the electromotive force, as given by the voltmeter, are sufficient alone to indicate the progress and completion of the charge. They are more reliable than the evolution of gas. My dynamo is a small Gramme shunt-wound, my voltmeter is Cardew's, a most reliable, simple, and valuable instrument, and my current meter a Siemens' electro-dynamometer.

7. I was at first much troubled with electrical leakage. The current escaped over the edges of the box, wet through

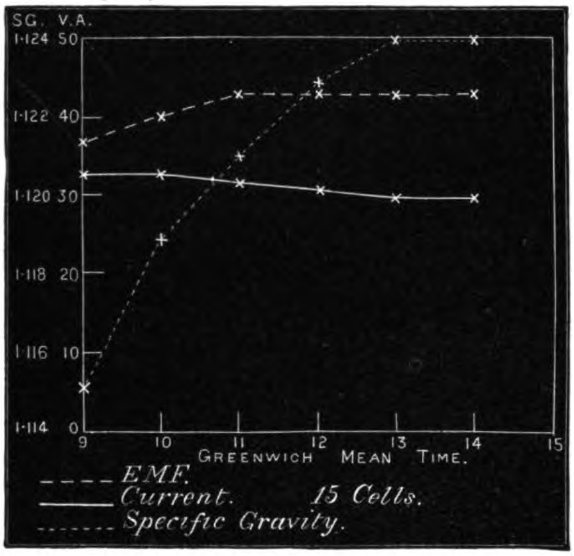

FIGURE 4.

creeping by capillary action, and the formation of moisture from the spray of the solution when bubbles of gas arose in the liquid and burst on the surface. This was quite cured by standing each box on three white porcelain supports of the form shown in the following figure, the cups being half filled with resin oil on Messrs. Johnson and Phillips's plan. It is now quite impossible to measure the leakage except with a delicate galvanometer, and it may be said to be practically perfect.

8. The E. M. F. of the battery at its terminals :—

When charging.......... .... 2·25 per cell.
When idle.................... 2·05 "
When discharging............ 1·90 "

The internal resistance[4] is, per cell :—

When charging.................. ·0060ω
When discharging.............. ·0017ω

9. But the latter varies very markedly with the strength of current of discharge. This is shown by the following experiment made with 23 cells of a smaller type than those described above, which are used in the post-office.

Current of discharge in ampères.	Internal resistance in ohms.
4·39	0·7608
7·25	0·4607
15·84	0·2816
25·07	0·1969

10. Thinking that this remarkable diminution of internal resistance might be due to the evolution of heat, I measured the temperature with a delicate thermometer.

Normal temperature of cell 12½°C. Current of discharge :—

5 ampères.... No alteration of temperature perceived.
10 " .... An exceedingly slight change.
16 " .... About 12¾°.
20 " .... Barely 13°.

3. The Parker-Planté process consists in immersing for a few hours the lead plates in a solution of nitric and sulphuric acids in these proportions—
Nitric acid.......... 1
Sulphuric acid.......................... 2
Water.. 17
before fixing in the cells. This not only chemically cleans the lead surfaces, but it favors the formation of sulphate of lead in such a way as to be readily converted into lead peroxide and spongy lead on the passage of a strong current through the cells. The formation of the cells is thus greatly expedited.

4. The term "internal resistance" means the effect of counter-electromotive force as well as of resistance to conduction.

Digitized by Google

The current in each case was kept on for 20 minutes, hence it is not due to heat. Since the internal resistance varies in this way, I now always take the internal resistance with the same current, viz., 10 ampères.

11. The capacity of these batteries certainly improves with age, and up to the present time I have seen no sign of decay or deterioration. M. Planté informed me that, though in course of time the peroxidized plate becomes very brittle, it is impossible to peroxidize it completely through ; there always remains a metallic core to give it strength. My experience of these plates confirms this. Up to the present moment I have made no careful measurements of the efficiency of my battery. I cannot do so without deranging the lighting of my house, and I regard observations on single cells as illusory for they are so very variable. I put in about 240, and I take out about 200 ampère-hours weekly, and I do not observe any change or fall in the electromotive force. When the electromotive force of these cells falls, it falls rapidly, indeed, almost suddenly. Occasionally one plate of a group becomes inactive from undue local action, or from bad connection (shown by the color). I remove this cell and put it in what I call a "hospital" cell, where it is brought into order either by a greater density of current or by reversal.

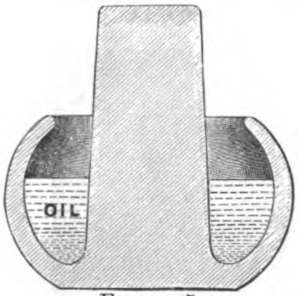

FIGURE 5.

12. Reversing has a great beneficial action on a cell ; it not only improves its capacity, but it removes any cause of irregular working. It is advisable to do this periodically. I have two extra cells, which enables me to have two cells always under reversal by means of the charging current. It takes from 1,000 to 1,200 ampère-hours to reverse my cells in the condition they are in at present, but this will vary with the amount of lead peroxide which has to be reduced to spongy lead. Hence at this time of year it takes a month or more to complete the operation, and it will take a year to reverse the whole battery. I have up to the present time reversed 16 cells.

A NEW APPLICATION OF ELECTRICITY.[1]

A NEW and interesting application of electricity, in a somewhat unexpected direction, has formed the subject of some recent investigations by Mr. Alfred O. Walker, of Chester.

Our readers may have noticed, in the autumn of last year, reports of a lecture read by Professor Lodge, of Liverpool, on the subject of "Dust." Papers were first read by Professor Lodge in this country, and the subject was afterwards more extensively dealt with in a lecture which he delivered at Montreal, during the meeting of the British Association.

In the course of these lectures the professor brought before his hearers the curious observations which he had made as to the effect of a discharge of high-tension electricity from a point, or points, into glass jars or other vessels containing dust of any kind in suspension. He also made interesting and striking experiments illustrating his remarks. Thus if a bell-jar be filled with a dense smoke of magnesia, by burning some magnesium wire inside it, a very long time elapses before the magnesia settles out and leaves the glass clear of smoke. But if a metallic point be introduced into the jar, connected by a wire to one of the poles of a good frictional, or induction electric machine, it is only necessary to set the machine to work, and almost instantly an extraordinary effect is observed inside the bell-jar. The magnesia smoke commences to whirl about and then forms itself into large flakes and strings which rapidly settle on the bottom and sides, leaving the jar perfectly clear of smoke. What would have taken several hours to settle in the ordinary course, is completely cleared and deposited in a few seconds. The same effect is produced if the jar is filled with any kind of smoke, that from thick paper, or from a cigar, being acted upon exactly in the same manner as the magnesia. Professor Lodge told his audience that he and his assistant had made experiments on a very much larger scale than those in the glass jars. Rooms had been filled with dense smoke and rapidly cleared in the above manner.

A report of one of these lectures appeared in our contemporary *Nature*, and was read by Mr. A. O. Walker. This gentleman is one of the partners in the well-known firm of Walker, Parker, and Co., lead smelters and manufacturers, and it at once struck him that in these observations and experiments of Professor Lodge might be contained the means of solving one of the principal problems with which a lead smelter has to deal, viz., the condensation of the "fume," or volatilized lead, from the furnaces. Various forms of apparatus have been from time to time proposed as "fume condensers," but with little or no success, the best results being so far obtained by passing the fumes from the furnaces through long flues and chambers. At the large works belonging to Walker, Parker, and Co., at Bagillt, in North Wales, the flues and chambers have a total length of over two miles, and still the condensation and deposition of the lead fume is far from complete.

Mr. Walker at once communicated with Professor Lodge on the subject, and the matter being considered very promising, it was decided at once to try experiments on a practical scale. These were carried out by Mr. Walker at the works at Bagillt, with the assistance of the manager, Mr. W. M. Hutchings. Professor Lodge himself gave scientific advice and assistance on special points. The results of the experiments, which were carried on during many weeks, were extremely satisfactory, and fully bore out Mr. Walker's hopes and expectations.

By means of large casks a wooden flue was constructed at right angles to one of the main flues of the works, and with a damper on the main flue it was possible to make any required amount of the fumes from a group of furnaces pass into and through the wooden experimental flue. This latter was provided with glass windows placed opposite one another for the purpose of observation. It also had dampers by means of which it could be filled with the furnace fumes and then closed at both ends, so that it formed a chamber representing the professor's bell-jars on a very large scale.

The electric machine employed was on the Voss system, the glass disc being 18 in. in diameter. It was worked in a small shed erected close to the experimental flue. One pole of the machine being connected with the ground, the other was connected to an arrangement of metallic points placed inside the flue, and exactly between two of the windows above mentioned. A well-insulated copper wire led from the pole to the top of a stout brass rod, which was fixed in the top of the flue, projecting some distance above it, and reaching so far into it as was necessary to sustain the discharge points in the desired position. This brass rod was fixed inside a glass tube of considerably larger diameter, in order to insulate it where it passed through the top of the flue. During the experiments several different arrangements of discharge points were used, as for instance a brass ball having spikes projecting from it all around, a ring with spikes fixed upon it pointing in all directions, a cross studded with spikes in a similar manner, &c.

The electric machine, being kept dry and warm in the shed, worked in a very satisfactory manner during all weathers, giving sparks some 4 in. in length.

The first experiments tried were upon the lead fume in a state of quiet ; that is, the flue was filled with fume by allowing a strong current of it to pass through from the main flue, and then simultaneously closing the inlet and

1. *Engineering* (London).

Digitized by Google

outlet dampers. The fume thus inclosed in the chamber, when viewed through the windows, appeared as a very dense fog or mist. Left to itself it took many hours to deposit. But as soon as the electric machine was set to work, the same action took place as with the magnesia in the bell-jar. Through the windows could be observed the same whirling movement around the discharge points, and in a few seconds the fog was seen changing into little flakes, like snow-flakes, which rapidly flew to the sides of the chamber, and were there deposited, till in an incredibly short time the "fume" had entirely disappeared from the atmosphere of the chamber, which was as clear as before the fume was let into it.

Further experiments were then tried as to the action of the electric discharge upon the fume in rapid motion as it is in the flues of the works. The damper in the main flue being closed, the whole of the pressure of furnace gases was turned through the experimental flue and allowed to stream out into the air. Then the electric machine was worked as before. No effect could be seen through the windows because the rapid current swept the fume onwards too fast to allow of any change being observed at that point. But at the outlet into the atmosphere, a few seconds after the discharge of electricity commenced, the effect was again very striking, the issuing fume again changing from fog into flakes. A glass plate held in the current before the discharge from the machine began, was only coated, after considerable time, with a thin film. A similar plate held in the current during the working of the machine was instantly coated over with flakes and large separate specks of fume. So much was the fume agglomerated by its passage past the discharging points, that on some occasions in perfectly calm weather some of it would fall to the ground immediately on leaving the exit opening of the flue. In short, the series of experiments proved that what took place under the bell-jar took place equally in the flue of a smelting works, with all the attendant circumstances of heat, moisture, and acid vapors.

The trials of various arrangements of discharge points seemed to show that, within certain limits prescribed by the power of the machine in use, the more points employed the better was the result, the points being spread as uniformly as possible over the cross-section of the flue through which the fumes are passing.

On the strength of the satisfactory results above stated, Mr. Walker decided upon taking measures to apply this new process of fume condensation on a full working scale at the Bagillt works. The necessary plant is now in course of erection, and nearly completed. The electric machines used will be on the Wimshurst system, with discs of 5 ft. diameter. Two such machines have been constructed specially for the purpose by Mr. F. J. Cribb, engineer, of Chester. They will be driven by a small steam engine, the whole plant being placed in a small building close to the main flue of the works, through which pass all the gases and "fume" from nineteen furnaces.

Mr. Walker proposes to extend the process in England and most European countries, and in the United States. It is intended to apply it to other branches of metallurgy besides lead-smelting, as, for instance, the condensation of zinc oxide in the manufacture of zinc-white, and the condensation of arsenic. But its principal field of usefulness will doubtless be in lead works, where so far all the proposed systems of condensers have either failed outright, or proved so costly to erect and to work, that the very imperfect results obtained did not render it worth while to continue their use.

The outlay for the requisite machines, etc., will be a very moderate sum, and the cost of running the apparatus even for large works will be limited to the wages of one man per 12 hours, and fuel for a boiler to develop the insignificant power required to drive the Wimshurst machines. There will be little chance of anything getting out of order, and in case a temporary breakdown of any kind takes place, the work of the furnaces will be in no way interfered with. This is, perhaps, the greatest recommendation of this process in the eyes of managers of works. Any one who has run a works, the draught in which depended on mechanical arrangements, as is the case where fume is to be condensed by sucking or forcing through water, knows what a constant succession of breakdowns and stoppages has to be encountered. Mr. Walker's process causes of course, no interruption of the proper draught in the flues, under any circumstances. Fume which is now carried forward through the longest flues, and escapes from the chimney, will be rendered so much denser by the action of the electric discharge that it will not be carried anything like so far by the draught, and will rapidly deposit itself. Thus, works which have now considerable flues may look forward to obtaining a greatly increased yield of condensed fume, while others which have not as yet considered it worth while to erect flues for the partial condensation to be obtained by their use, will probably find it advantageous to do so, when, by so simple a process as the one in question, they can obtain from a moderate length of flue a greater yield than could otherwise be looked for from a very great length.

When Professor Lodge was carrying on his experiments on "dust" from a purely scientific point of view, it is not likely that he had any idea how soon his results would become of practical commercial value; and the speedy turning to technical utility of these experiments, owing to the sharpsightedness of Mr. Walker, is but one more of the many instances demonstrating the unexpected and often surprising manner in which "pure science" of one day may be very valuable "applied science" of the next.

DESCRIPTION OF A LARGE SECONDARY BATTERY PLANT FOR GENERAL COMMERCIAL DISTRIBUTION.[1]

BY E. P. ROBERTS, M. E.

(General Manager of the Brush-Swan Electric Light Co., of Cheyenne, Wy.)

1st. Description of the storage plant.—2d. Direction for erecting and maintaining storage batteries.—3d. Remarks respecting storage batteries and their field of usefulness.

A description of our entire plant, both arc and incandescent, was published in the *Electrical World* of February 28th, 1885, and from that article will be quoted a description of our battery plant.

The Brush-Swan Electric Light Co., of Cheyenne, was formed in the fall of 1882, and was the first Brush-Swan company formed to use the Swan lamp in conjunction with the Brush storage battery and arc system. Storage batteries were put in operation early in 1883, and at the present time 99 batteries and 1,500 lamps are in operation, distributed over an area about one mile square, the charging station for the batteries being about one-quarter of a mile outside the north-west corner of the square, and over 300 of the lamps being in the south-east corner.

BATTERY PLANT.

"On each block—sometimes on every two blocks—is located a small portable house, in which are placed all the batteries furnishing light for said block. A partition divides it into two parts, one for the batteries and the other for the meters and switch-board. A plug switch is used in order that any combination may be readily effected. Cable connections permit coupling batteries together as desired. An extra battery is kept in each house for use in case extra light is required.

"The batteries are placed on string pieces 2 inches by 4 inches by 10 feet; each cell rests on four porcelain insulators, and the string pieces rest on Western Union insulators, with pins set in cross-pieces. Three sizes of batteries

1. Read before the American Institute of Electrical Engineers, May 20, 1885.

Digitized by Google

are used, 1, 2 and 3, with capacities of 20, 40 and 80-lamp hours respectively.

"Three charging circuits are used, two to private residences, where Nos. 1 and 2 batteries are used, requiring from 7 A. M. to 1 P. M. to charge them with a 10 ampère current, and one circuit to the business part of the city, where batteries are used. As these batteries are much larger, a longer time is required to charge them, and, therefore, they are charged from 7 A. M. until 3 P. M. by a 65-light dynamo. They are then connected by switch, as desired, for the night, in some cases three batteries being connected for quantity.

"At dark the charging circuit is looped in with the all-night outside arc circuit, and the charge thrown on about 20 meters, and by the connections for quantity controls about 50 batteries; thus they are left until daylight, when the arc circuit shuts down. By this means the batteries obtain considerable charge; they are then disconnected and charged separately during the day."

Directions for Erecting and Maintaining Storage Batteries.

A. CAREFUL INSULATION.

1st. Battery as a whole well insulated from the earth.

2d. Each cell insulated from all others, excepting, of course, through the proper channel for the passage of current.

3d. The positive and negative in each cell to be insulated from each other except through the liquid. No connection by moisture on the upper edge of the containing box.

B. REGULAR CHARGE AND DISCHARGE.

1st. Fill the battery every day.

2d. Discharge the battery every day.

3d. Never over-charge.

4th. Do not exhaust completely.

C. DO NOT EXPECT BATTERIES TO TAKE CARE OF THEMSELVES.

1st. Test electromotive force of each once a week with a voltmeter.

2d. Test each cell with an acidometer once a month.

3d. Each day see that each cell in each battery fills in the same time.

4th. Keep plates covered with liquid.

5th. Examine all connections frequently.

D. Keep extra cells complete and charged, with which to replace defective ones. Do not put uncharged plate or cell in battery in regular use.

E. Do not "box in" batteries. Give free circulation of air.

F. Keep all connections, switches, etc., as far as possible away from batteries.

G. Study the cause producing a new effect, and attend to details.

REMARKS.

After considerable experience with storage batteries, my conclusion is that they have been both praised and belittled too much. That the service can be good is certain; but that for a closely settled district they are preferable to dynamos is not, according to my experience, correct.

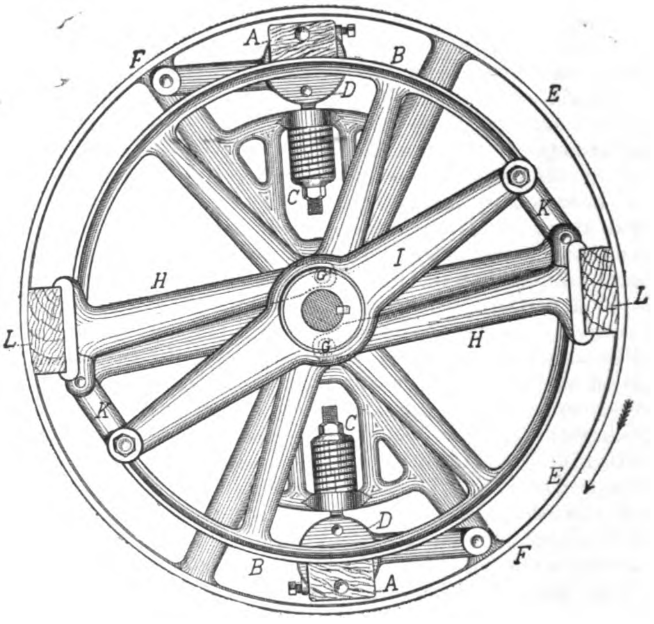
Experience teaches the manufacturers many points in design and formation which greatly increase the reliability of secondary batteries. Experience in handling them teaches men many little matters which greatly assist in keeping the batteries in good condition.

My plan for our new station about to be erected will show, more forcibly than a lengthy disquisition, my ideas respecting secondary batteries in connection with stations for the distribution of electrical energy.

A building is to be erected near the business portion of the city, from which our arc lights will be supplied, and in which also will be placed dynamos for running the incandescent lights in the business district. Batteries will be used in portions distant from the station. These will be charged from 3 A. M. until 7 A. M. with a 15-ampère current. At the station will be several large batteries, which will be used for day lighting or in case of a breakdown.

A GOVERNING PULLEY FOR DRIVING DYNAMOS.

THE irregular speed of the steam engine, as now constructed, has brought into the field various devices to overcome the difficulty. Among others who have directed their attention to this subject is Mr. A. Campbell, well known as a builder of printing presses. Being unable to secure an even blast of air, which was essential to the perfect working of a sheet delivery apparatus for a new press, on account of irregular speed, he was led to invent what he calls the "planet pulley." The uniformity of speed attained by its use (the engine varying 12 per cent. at times) has convinced the inventor that it will prove very acceptable in connection with electric light plants. The necessity of some such device has been keenly felt where dynamos are run in series. The maintenance of uniform speed among the different generators in such cases has heretofore proved a difficult problem.



The accompanying illustration shows the general construction of this pulley, which comes under the broad head of what are known as friction pulleys, except in this case it is a delicately controlled friction that produces absolutely uniform speed.

When at rest the block, A, of the feeling brake is drawn into firm contact with the smooth surface of the supplementary pulley, B, by the spring, C, through the governor ball, D, attached to the arm of the driving pulley, E, at the point, F, binding E and B firmly together. On the hub of B are two studs, G G, as shown by dotted lines. Upon these the arms, H H, are hinged, the outer ends of H being connected to the brake carrier, I, by the links, K K. The brake carrier, I, is keyed to the shaft, and the pulleys, E and B, turn freely upon it. On the opposite side of E are duplicates of the pulley, B, arms, H H, link, K K, blocks, A A, and brake carrier, I. By this arrangement the pulley, E, the governor, D D, blocks, A A, and springs, C C, are embraced between the actuating mechanism, and could be turned freely, provided the blocks, A A, were removed from contact with the rim of the pulley, B. This would occur when in motion, provided the speed was such as to have the centrifugal force imparted to D, sufficient to overcome the spring, C; B and H being linked to the carrier, I, and this keyed to the shaft, they would all then turn freely

without driving the pulley, E; but the instant E slows up sufficient to allow A to bear on B, B would be retarded, causing the arms, H H, to be thrown outward, and bringing the blocks, L L, in firm contact with the inside of the rim of the pulley, E, picking it up and thereby increasing the speed; but the instant it reaches that point where the spring, C, and the work done are equal to the centrifugal force of the ball, D, a sliding action takes place equal to the variation of the line shaft above a fixed speed.

One of the great advantages to be derived from the use of this pulley is that a dynamo may take its power from an engine used for other machinery, and subject to a fluctuating load. Various tests have been made, proving its governing scope; for instance, with 15-h. p. on a three-horse pulley the main load has been cut off, and the engine allowed to run at double its normal speed, without causing a variation of more than three per cent. They are not, however, constructed with a view to a greater change than 10 per cent. of the load. With half the load thrown off, the speed is increased less than one per cent. This variation is a uniform increase or decrease, not an average.

ELECTRIC FIRE-ARMS.

The application of electrical ignition to fire-arms has been brought to such a state of perfection that it is confidently predicted that electricity will eventually supersede the percussion system, now almost universally used for sporting and military arms. In order to do this, however, electricity must be thoroughly proved to possess advantages in various particulars, and, at the same time, be free from objections which will naturally arise in the minds of those who are most familiar with its action.

On the part of the advocates of electric fire-arms, it is claimed that they can be manufactured in quantities for one-third less than those now in use, the principal reason being that the lock is entirely dispensed with, it being superseded by a battery, at a much less cost, which will ignite several thousand cartridges before it is exhausted. The guns can also be made both shorter and lighter for similar reasons. The cartridges can also be made considerably cheaper, no fulminate of mercury being required. A paper or linen case may also be substituted for the metallic shell now required in breech-loaders, the latter being necessary in order to withstand the shock of the firing pin, which strikes the base with a momentum of 18 pounds. The danger arising from poisoning by fulminate of mercury, as well as from accidental explosions either in manufacture or transportation, is entirely obviated or materially lessened.

One of the most important advantages, however, is the ignition of the charge at the base of the projectile, so that the powder burns toward the rear, and combustion is more perfect. This is of great importance in rapid firing, as the gun does not foul so readily, while the explosive force is also greater. The absence of any recoil is another feature due to the ignition of the forward part of the charge. As but the slightest pressure is necessary to close the circuit, the aim is not disturbed, either by pulling the trigger or the blow of the firing-pin.

A cartridge adapted to electrical ignition was invented by E. A. Monfort in 1882, and is adapted to guns of all descriptions. In small arms intended for firing from the shoulder, a small primary or secondary battery weighing about three ounces is enclosed in an ebonite box, and placed in the stock of the gun, from which the conducting wires are led to contact surfaces inside of the cartridge chamber, in one of which a simple circuit-closing device is provided in lieu of the ordinary trigger, which is arranged to be manipulated by a slight movement of the finger. A suitable device is also provided for keeping the circuit open, when not required for use, to provide against accidental discharge. The terminals are so located in the cartridge chamber that the conductors in the cartridge are brought in contact with them in whatever position it may be placed. The cartridge is provided with two conducting wires, leading from the base into the powder. The apex of the loop is formed of a fine platinum wire, which, being heated to incandescence upon the closing of the circuit, instantaneously ignites the powder, and the piece is discharged. Mr. Monfort has since made several improvements, both in guns and cartridges, the patents for which have been assigned to the Universal Electric Arms and Ammunition Company.

These results are readily attained upon an experimental scale, but it is only by practical experience that we may determine whether such a state of universal perfection can be reached as to render the electric fire-arm a reliable weapon under all circumstances.

COPPER AND BRASS.[1]

Copper was the first metal wrought into arms and implements in the territory which is now the United States, if the testimony of the relics of the days of the Indian occupation, and of the records of the Catholic missionaries, does not deceive us. The red metal which underlies the State of Michigan in such priceless deposits early caught the eye of the savage warriors who threaded the forests of the north in pursuit of game and built their camp-fires on every hill. The stone hammers of the early race of men had been employed upon the metal; and the Jesuit fathers who marched with the cross of their religion in advance of the soldiers who bore the lilies of France found great quantities of it worn as ornaments and shaped into tools and weapons by the red heathen whose conversion to Christianity they sought. Had the white man who succeeded to the occupancy of the soil also inherited the civilization of the red man, it is probable that he, too, would have expended his art first upon the working of red copper, before attempting to utilize the less attractive and more refractory metal which now claims his more diligent attention; but the white man brought to America the science and arts of an older and higher civilization, and copper claimed his attention less at the outset than the denser metal. That has not, however, prevented copper from assuming the important rank in the arts of the country to which its qualities entitle it. Its manufacture is one of the greatest industries of the United States.

The first copper mines were opened in Connecticut; and the state employed its convicts for a period of sixty years, ending about 1830, in getting out the metal in the town of Simsbury. The ingots of metal were sold to the mint and to the smiths; but at first by far the larger part was exported to Europe to be manufactured. After 1812, when a duty of 35 per cent. was levied upon manufactures of copper, there was less of metal exported, and more of it made up into plate and utensils for use on this side of the water. The industry developed the fastest in the eastern and middle states. In 1870 there were 391 copper and brass factories in operation, employing 5,600 hands, and producing a value of $15,000,000 in finished goods annually, there being of these factories 29 in Connecticut, 44 in Massachusetts, 85 in New York, 81 in Pennsylvania, and 21 in New Jersey. Ansonia and Waterbury, Conn., became the principal centres of the manufacture.

Pure copper is one of the softest of the metals, and is easily rolled into plates for use. It is in the form of plates principally that it is employed in the arts. Its most important use is in the sheathing of the bottoms of wooden ships to protect them from accumulations of barnacles and shell-fish and the ravages of the borers. The navigators of the early centuries had great trouble with their ships on account of the fouling of the bottoms. It was finally suggested that the protection of the part of the ship below the load line with sheet lead would prevent incrustations,

1. *Pottery and Hardware Reporter.*

Digitized by Google

and that material was used for a while. In 1761 the "Alarm," a frigate in the royal navy, was sheathed with copper, which was found to answer the purpose very much better. After a series of years, it was found that pure copper, while protecting the ship, was itself rapidly eaten away by the chemical action of salt water, which made its renewal necessary. This was expensive, and shipping men cast about for some improvement of the process of sheathing. A curious experiment was made in response to a suggestion by Sir Humphrey Davy. This was to place strips of iron under the sheets of copper, which would be corroded by the galvanic action rather than the copper. The invention worked beautifully; the copper was preserved and money saved. But, quite unexpectedly, it was then found that the copper, no longer dissolving in the sea, became covered with barnacles as badly as the wooden bottoms had been before. So the shipbuilders went back to pure copper. After a while, however, an alloy of copper was invented by mixing with it 40 per cent. of zinc, which answered the purpose of sheathing admirably. The alloy was a species of brass. It was called "yellow metal," and still retains the name, and is now universally used for the coppering of wooden vessels. The metal is very soft, and is rolled cold. It is worked down very gradually and carefully from the ingot, being annealed after each rolling, and cleared of oxide by pickling in a bath of diluted sulphuric acid. Owing to the high price of labor in this country, sheathing has been more expensively made in the United States than abroad until within a very few years. Of late the price has been so reduced that the former large importations of it have greatly fallen off, and the sheathing used by American shipbuilders is virtually all American-made. The bolts and nails by which copper sheathing is fastened to the ship are cast solid.

Sheet copper is a very popular material for boilers and cooking utensils in domestic use. The metal resists the action of the fire better than tin and sheet iron; it is, therefore, applied to the construction of many forms of manufacturing apparatus which come into contact with fire, such as retorts and pipes, vacuum-pans, condensers, and boilers in distilleries, sugar-refineries, and other factories. The smaller utensils are formed from the sheet metal by hammering, and by the process of spinning up. The copper becomes very dense and brittle in the smithing process, and has to be annealed constantly as the work goes on. In boiler-making the plates are either united by lapped joints, soldering or riveting, and sometimes by more than one of these methods.

Copper is more extensively used in the form of brass than in its pure state. By admixture with a certain proportion of zinc it gains beauty and durability, and is generally preferred in that form. The best proportion of the metals is two of copper to one of zinc, which makes what is called eight-ounce brass; that is, eight ounces of zinc to 16 of copper in the pound. Sixteen-ounce brass, the two metals being equal, is a beautiful golden alloy, called "prince's metal." Other combinations are made to produce pinchbeck, Manheim gold, and other alloys suitable for cheap jewelry, and ware for gilding and silvering. Brass is as agreeable metal to work as pure silver. In thin plates it can be stamped and embossed in any form. It spins up beautifully in a lathe. It can be drawn out into delicate wire; and is so malleable that it can be beaten out almost like gold-leaf itself for the purpose of cheap gilding. The metal is susceptible of a high polish. It does not rust by exposure, and has a great deal of the beauty of gold. It is the universal material of which chandeliers and gas fixtures are made, being susceptible of rich coloring, bronzing and silvering by chemical processes, and of shaping into the most elaborate forms by stamping and embossing. Brass was at one time the exclusive material out of which the works of clocks were made. Steel works are now beginning to be used to a very large extent; but brass holds its own for all cheap clocks, and indeed is popular in every grade of timepiece up to the great machines put in the towers of our city halls and churches. Its beauty, and freedom from rust, insure its popularity.

STEAM ENGINES FOR ELECTRIC LIGHTING.[1]

The production of engines for electric lighting, is now becoming recognized as an important branch in many engineering establishments. In few cases have special designs been got out for this work. Portable and semi-portable engines have been largely used, but as electric lighting gets beyond the experimental stage, engines of these types become inadmissible for permanent installations, and separate fixed engines and boilers are required. There are doubtless, at the present time, many engines in the market which admirably fulfill all the required conditions, but there are also a great number which fall lamentably short of this, so that a brief discussion of the principal points to be kept in view in designing engines suitable for electric lighting may be acceptable. The points we deem worthy of primary consideration are steadiness in running, good governing, the capability of making long runs without stoppage, and, not least, economy in working. By steadiness in running we mean the maintenance of a uniform angular velocity of the crank-shaft during a revolution. It follows from the nature of the motion of the crank and connecting-rod that this should be variable, and it can only be made uniform by the employment of a heavy revolving mass as the fly-wheel, or by coupling more than one engine to the same crank-shaft, the cranks being set at the angle giving the most uniform effect. In a pair of engines this angle is by no means the almost universal one of 90°, and as electric lighting engines are not required to reverse, there is no advantage in retaining that angle, and the most advantageous position should be determined for each particular engine, varying as it does with the speed, the grade of expansion, and the weight of the reciprocating parts. The reduced weight of the fly-wheel and the increased uniformity of motion thus attained are well worth the trouble of finding the correct angle. With regard to governing, we have two cases to consider, *i. e.*, we may have either a practically uniform load on the engine, or one liable to sudden and considerable increase or decrease. In the first case it is certainly advisable that the governor should actuate a throttle-valve, but in the second we have either to control the engine by an automatic expansion gear, or by the hand of a careful engine driver, who varies the supply of steam to the engine, either at the stop-valve or at the expansion gear. It is needless to say that when the variation is at all considerable the latter should be the plan adopted. Both the governors and the fly-wheels of steam-engines are employed to secure uniform rotation, the fly-wheel serving to equalize and reduce a constantly recurring and periodic irregularity, whereas the duty of the governor is to adjust the work done by the engine to the work to be performed, and thus prevent a continuous acceleration or retardation in speed. Sensitive governors have their value considerably reduced by insufficient steadiness in running, due to the use of too light fly-wheels. To secure runs of long duration we have to pay particular attention to the lubricating arrangements, allow ample bearing surfaces, and, what is perhaps more important than all, put in first-class workmanship. Arrangements should be made for lubricating the crank-pins when the engine is running. This matter presents no difficulty in vertical engines, or, again, in engines having overhung cranks, while for engines with double-throw crank-shafts the difficulty is not at all serious. All the other bearings about an engine of ordinary design present no special difficulties as regards lubrication. A considerable discretion should always be exercised as to the choice of a lubricant. The conditions upon which economy in working depends are so generally known that we need not enlarge upon them

1. *Mechanical World.*

Digitized by Google

here further than to say that the conditions of electric lighting work are favorable to obtaining the best results, Many installations are now being laid down with the engines and dynamo machines in duplicate. This is certainly a safe although an expensive plan. In such arrangements the engines and machines should be worked alternately, as it usually happens when one engine is kept in reserve and not regularly worked that it is not ready when required.

A NEW STANDARD CELL.[1]

SINCE October last I have made some experiments on the zinc-alkali-copper oxide cell, with a view to determine the practicability of some modification of it.

The fact that copper and iron, and perhaps some other metals, dissolve in potassium (or sodium) hydrate when used as cathodes, suggested to me the possibility that the formation of the alkaline cuprate might occur at a definite and practically convenient difference of potential between the electrodes immersed in the alkaline bath. As a matter of fact, I find that a cell mounted with amalgamated zinc, potassic hydrate and metallic copper, gives, when charged until a blue color appears, a deflection of 170 divisions on the scale of a Thomson galvanometer; the Daniell, mounted with saturated zinc sulphate and copper sulphate, giving 156 divisions. The zinc-alkali-copper cell is joined by a double key to charging cells and to the galvanometer, a resistance of over 9,000 ohms being included in the circuit of the latter.

The proper shunt is, of course, employed. This deflection of 170 divisions seems to be invariable, and the cell experimented upon promises to be a desirable practical standard of electromotive force. Its excellence appears to consist in the fact that the cuprate produced breaks up before it diffuses to the amalgamated zinc, depositing oxide of copper, which settles. The zinc is suspended about an inch above the copper—which is a spiral ribbon, exposing about two square feet of surface—and the resistance is less than an ohm. I have used a 10-per-cent. solution of "depurated" potassic hydrate. After some trials it is found that the shifting of the cell from the charging source to the galvanometer circuit may be done leisurely, as the electromotive force does not seem to begin to fall off for some minutes. Further testing of the effect of changes of temperature, strength of solution, etc., is in progress. Thus far the temperature of the cell has been allowed to vary very little, not enough to affect the readings. I offer this preliminary note as of possible interest to your readers. This type of cell would be admirably adapted to furnish any desired multiple of its electromotive force.

Rutgers College, New Brunswick, N. J., June 18.

ABSTRACTS AND EXTRACTS.

SAFETY OF ELECTRIC LIGHTING.

THERE are, without doubt, numerous cases in which the electric light can not only be used more economically than gas or oil—that is, with regard to the total amount of illumination given out—but where it is, in addition, possessed of a far more important quality, that of (comparatively) perfect safety. The most notable instance of this will occur at once to the reader's mind, since for use on board steamships, whether passenger or cargo boats, this form of illumination stands unequaled. There can be little or no doubt that the recent destruction by fire of the steamship "Maasdam" (caused, it is said, by a naked light being brought too near the cargo of petroleum oil), might, nay, would have been entirely averted, had only the vessel been provided with glow lamps, and the needful machinery for their maintenance. Apart, therefore, altogether from their superior lighting power and consequent greater comfort, the item of safety is a still stronger argument for their use in comparison with the often dangerous and always unpleasant oil lamps, which the public and those who live on the sea have for too long endured. We also note a recent installation of glow lamps in a large distillery, where constant care had previously been needful in the use of gas, by reason of the inflammable spirit fumes evolved during the process of distillation. For all such purposes, therefore, this method of lighting cannot be too highly recommended; and when, as we believe is the case in this instance, there is a clear monetary profit to be obtained by its use, one would be tempted to consider the tradesman or manufacturer extremely short-sighted in failing to avail himself of such advantages. In all manufactures where mineral oils are much used, in sugar refineries (for the vacuum pans, for example), in the majority of textile factories, and in countless other places of industry, we are convinced that electric lighting will be found to give the greatest benefits with the fewest risks. —*Mechanical World.*

LARGE OR SMALL DYNAMOS.

IN a work on the electrical transmission of power, M. Marcel Deprez and M. Japing state that a great many problems connected with this subject may be solved with the machines already constructed and the means actually at command, and also that the future is to large machines. Commenting on this, the *Bulletin International des Telephones* observes that electric lighting experiments in England and Austria with alternate-current machines do not appear to have settled the question. Edison with his continuous-current machines does not seem to have exceeded 40 or 50 h. p., a long way off 200 h. p.; and M. Marcel Deprez's experiments at Creil have special interest in this connection. Our contemporary, however, asks if, in every respect, large machines give comparatively better results than small. It is intended that the generating machines at Creil shall weigh from 35 to 40 tons for a current of 7,500 volts and 20 ampères, equal to 200 h. p. at starting. The receiving machines at Paris will weigh from seven to eight tons, and communicate to the shaft an available work of 30 to 35 h. p., whence it follows that the weight per h. p. will be about 175 kilograms (31-2 cwt.) for the generator, and 200 kilograms (nearly 4 cwt.) for the receivers, under the most favorable conditions. Now, in the present machines, such as the Gramme, for instance, the weight per h. p. does not attain 40 or 80 kilograms (rather over 7½ or 15 cwt.), according as they are used as generators or receivers. Therefore, the mean weight or matter per h. p. in large electrical machines will greatly exceed that of small machines. Here is a contradiction not generally met with. But, adds the *Bulletin*, this is not the first time that electricity quits beaten paths; and such small details will be no bar to ultimate success.

ELECTRIC LIGHTHOUSES.

SOME light is thrown on the important question of the availability of electricity as an illuminant for lighthouses in a recent paper reporting results of the French scientist M. Allard's experiments. In ordinarily clear atmospheric conditions it has been found that the light at Dunkirk, which is obtained from mineral oil and is of 6,250-candle power, is visible 32 miles, while an electric light of 125,000 candles is visible 46 miles. Thus an increase in the illuminating power of 20 times only increases the distance penetrated 13 miles, or 42 per cent. But in air of less than ordinary transparency the electric light can be seen only 2½ miles further than the mineral oil light—an increase of only 24 per cent. In very foggy weather the electric light penetrates but little over half a mile further than the oil light.

The electric light from this showing is not, after all, so very much better for lighthouse purposes than mineral oil,

1. *Science.*

Digitized by Google

But it should be remembered that the cost of an electric light of 125,000 candles is, according to the computation of both French and English engineers, from four to six times less than that of an oil light of equal penetrative power. For this reason the electric light bids fair to become the future illuminant for all great lighthouses. If such lights as that of the new Eddystone, with its electric beam of 160,000 candles, or the electric Lizard, which has been seen by a ship seven miles distant in a fog, were more numerous on the sea coast the perils of the mariner would be greatly reduced.—*Manufacturers' Gazette.*

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents. Anonymous communications cannot be noticed.

The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.

In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.

Sketches and drawings for illustrations should be on separate pieces of paper.

All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

THE RAILWAY SIGNAL DECISION.

[35]—I have no commission to defend the Supreme Court; but think your recent editorial comments upon its decision in the electric signal case, are unduly alarming to the owners of inventions; and therefore I will venture to suggest a more cheerful interpretation than yours.

The Court decided nothing but a question of fact: decided only, that the Hall contrivance does not infringe the Pope patent. To support this conclusion the Court assigns two independent reasons.

1. Hall does not use the insulated sections of track which Pope uses for circuit-closers, and includes in each of the combinations covered by his respective claims.

Now such an omission has been fatal to any charge of infringement, of any combination claim, ever since the decision in Prouty *v.* Ruggles (16 Peters, 341), decided in 1842, unless the defendant used an equivalent for the element which he omitted. The Court found the Hall circuit-closer not to be an equivalent of the Pope circuit-closer, because it was not known at the date of the Pope patent. That such a fact is fatal to equivalency, was first declared by Justice Clifford in the case of The Union Sugar Refinery *v.* Matthieson (2 Fisher, 629), decided in November 1865; and was repeated by the same warm friend of patent-rights in the later cases of Seymour *v.* Osborne (11 Wallace, 556, 1870), Gould *v.* Rees (15 Wallace, 193), Gill *v.* Wells (22 Wallace, 31) and Imhauser *v.* Burk (101 U. S., 656, 1879). In all of these later cases, Justice Clifford spoke for the Supreme Court. The doctrine is one which I do not find it possible to like; but it is not a new doctrine, and, during all its twenty years of life, it has generally been quite a harmless one.

2. The combination of Hall differs from that of Pope in respect of mode of operation; because Pope's combination is so arranged that every circuit, when closed, differs in length, and therefore in resistance, from every other circuit when closed; whereas all of Hall's circuits are of precisely the same length and resistance To effect this improvement, Hall uses the earth for a third line conductor, and combines the two line conductors of Pope with each other, and with the earth, in a different way from that in which Pope combines his two line conductors together.

Now these differences of combination seem to me to be undeniable; and they seem also to be material, because they result in different modes of operation, having widely different degrees of utility. There never was a time, since the foundation of American patent law, when so wide a difference in mode of operation was not fatal to infringement. See Smith *v.* Downing (1 Fisher, 83, 1850) and Eames *v.* Cook (2 Fisher, 149, 1860.) A suit for infringement never could be sustained on a combination claim, where the defendant combined all of the elements of the patented combination, but combined them in a substantially different way. Gill *v.* Wells (22 Wallace, 14, 1874). Changing the relative positions of the parts of an apparatus averts infringement, if the change of position results in a substantially different mode of operation, even though the function of the apparatus remains the same. Brooks *v.* Fisk (15 Howard, 221, 1853).

The conclusion of the whole matter is that the youngest of the doctrines of law involved in the electric signal case is nearly twenty years old, and most of them are as old as the patent system itself. Had Justice Bradley or Justice Blatchford written the opinion, it would probably have been put into more familiar sentences and phrases; but the decision would have been the same, unless the writer had been authorized by the Court to depart from the precedents. ALBERT H. WALKER.

HARTFORD, Conn., June 6, 1885.

[It does not seem to us that Mr. Walker's letter exactly meets the point which we intended to make in our editorial of last month. He says:—"The Court found the Hall circuit-closer not to be an equivalent of the Pope circuit-closer *because it was not known at the date of the Pope patent.*" In Mr. Walker's very excellent *Text Book of the Patent Laws*, we find three tests of equivalency laid down. First, the equivalent device must perform the same function. There can be no question that the devices of Pope and Hall were the same in this respect, the function being the closing of an electric circuit by a moving railway train. Second, it must perform the function in substantially the same way, "not necessarily," says Mr. Walker, "a theoretical scientific sameness," but so nearly similar that the respective devices may be interchanged in the combinations, and still perform the required function "with a result that is beneficially the same." In the case under consideration the conditions require that the electric circuit shall be closed by or upon the passage of the train, and remain closed long enough for the signal to be brought into position, say three or four seconds. Pope's device accomplishes this, and so does Hall's, and these are only two of a large number of more or less similar devices, which are equally well adapted to the purpose and may be substituted for each other at will, without in the least affecting the result. Third, the device must have been known at the date of the patent. This brings us to the real point at issue. What is meant by being "known" at the date of the patent? Must the new element be something essentially novel, either in principle, structure or mode of operation, or need it be "new" only in the technical patent-office sense, that of being a trifling improvement, modification or equivalent of some detail of an existing device? In the present case, the circuit-closer employed by Hall was a contact-spring, which was made to press against a contact-point by the long arm of a lever, whenever the short arm of the same lever was depressed by the weight of a moving train. A retarding device was employed to prevent the too sudden recoil of the contact-spring. All this was familiarly known in the art, as the evidence in the case showed. But the particular construction of the retarding device which, in combination with the lever circuit-closer, was patented by Snow, after the date of Pope's patent, and which was used by Hall, involved nothing more than the substitution of an atmospheric dash-pot, consisting of a piston moving within a cylinder, for the bellows or the equivalent clock-train and fan which had been used in prior circuit-closers. The cylinder and piston, technically speaking, was doubtless enough of an improvement over the bellows and other like devices to support a limited patent, although it was in itself a familiar form of retarding device; but it seems to us that to hold this minor improvement in an accessory device appertaining to a known form of circuit-closer, to be sufficient to constitute the entire circuit-closer an element "not known at the date of the patent," and to argue therefrom that an otherwise novel combination is not infringed when it is used, is an entirely new doctrine in patent law, and one likely to lead to momentous consequences. If the mode of operation, or the result sought to be attained, were in the least affected by the change, there might be some reason to suspect that there was an element of novelty in the circuit-closer, but we do not understand that it is pretended that such is the case.

Mr. Walker, following the opinion of the Court, contends "that the combination of Hall differs from that of Pope in mode of operation, because Pope's combination is so arranged that every circuit when closed differs in length, and therefore in resistance, from every other circuit; whereas all of Hall's circuits are of precisely the same length and resistance," and adds:—"These differences of combination seem to me to be undeniable, and they seem also to be material, because they result in different modes of operation, having widely different degrees of utility." Why are they material? The equalization of the resistances is no part of Pope's invention, and is not even mentioned in the claims of his patent. Professor Moses G. Farmer, the complainant's expert, testified, without contradiction, that it was not at all essential to the operation of Pope's invention that the resistances should be equalized; and, moreover, it was in evidence that a certain signal

Digitized by Google

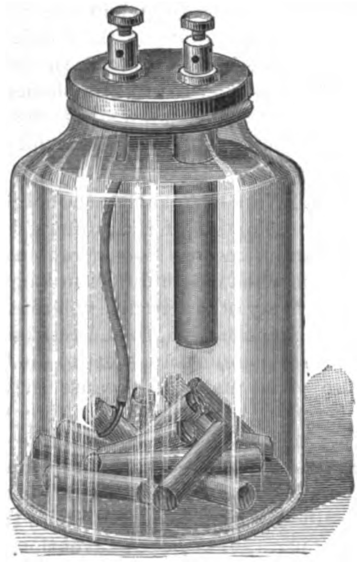
plant was in actual and successful operation with unequalized resistances. It was also proved that the very system of equalizing circuits employed by Hall was first made known by Pope, in a publication issued in 1869, and that Hall had chosen to apply it to his signals as one method out of several which he might have used, all public property and all equally well known. Hall's expert, Professor Morton, himself testified that the equalization of the circuits in conjunction with Pope's method was within the common knowledge of any skilled person, and required no invention whatever to apply. Suppose Pope had said in his specification:—"The circuits should be made of very large iron wire, as their resistance will thereby be reduced and the operation of the mechanism facilitated," and Hall had discovered that a smaller, instead of a larger wire could have been used with like advantage, provided it was made of copper, which is a better conductor than iron. Would that have avoided the patent? Certainly it would, according to the reasoning of the Supreme Court and of Mr. Walker.

The new result which was accomplished by Pope was the actuating of many widely separated signals from a single battery. To effect this result the only essential requirement was the extension of two conductors from the battery along the track, so that a circuit which should include the particular signal required and this common battery could be completed at any required point. What was patented was the least number of indispensable elements in combination by which this result could be effected. What was described was "the best mode in which the patentee has contemplated applying that principle," as required by statute. But the Supreme Court now says that a difference in the particular well-known means selected by the defendant to carry out a certain detail of practical application, not claimed as a part of the complainant's invention, and in no wise essential to its beneficial operation (inasmuch as it may be, and has been, omitted altogether), constitutes it a different invention.

Mr. Walker says:—"There never was a time since the foundation of the patent law when so wide a difference in the mode of operation was not fatal to infringement." We must confess ourselves unable to see any difference whatever in the "mode of operation." The mode of operation is the closing at different points on a railroad of the circuit of a common battery, so as to traverse the electro-magnet of a particular signal. What has the resistance of the circuit to do with the "mode of operation," unless it in some way affects the result? What has the equality of the different circuits to do with the "mode of operation," unless an inequality would *necessarily* affect the result? If it has nothing to do with it, what becomes of the "substantial difference" in the mode of operation referred to by Mr. Walker?—EDITOR.]

A CHEAP AND EFFECTIVE BATTERY.

[36]—A cheap, simple and efficient battery, suitable for the use of experimenters and amateurs, has long been needed. I have worked on the problem myself for several years, and have obtained very satisfactory results from one constructed as follows:—



Take an ordinary glass fruit-jar, fitted with a cover of wood or hard rubber, and place in it a number of pieces of electric light carbons, hundreds of which can be picked up in the streets every morning after the lamps have been trimmed. The connection between the carbons and the binding-screw on the top of the cover is best made with a gutta-percha covered wire, having its lower end bared and wound tightly round and secured to one of the carbons, thus making a connection with all the other pieces in contact with it. A piece of amalgamated zinc of any convenient size or form is suspended within the jar, from the wooden cover, and has a binding-screw attached to it.

The jar should be filled about two-thirds full with dilute sulphuric acid or other suitable solution. I find that the electropoion fluid or bichromate solution does very well.

I hope you will find room to publish this, as I think it will be of use to many amateurs. The whole battery complete can be made for about 20 cents, and it will give a good current on a closed circuit for a long time. I now use this battery in preference to all others. C. E. MEILLORET.

13 Fifth street, Brooklyn, E. D.

CONSUMPTION OF COAL BY STATIONARY ENGINES.

[37]—In the May number of the present volume, the article entitled Electric Motors on the Elevated Roads—Corrected Figures, Mr. Curtis in speaking of the amount of coal required by stationary engines states that 2.25 or even 2.50 lbs. of coal per h. p. hour is an extreme figure, and that 1.75 lbs., the amount given by Prof. Farmer, could not be counted upon. The writer upon making inquiries, obtained from the Corliss Steam Engine Co. a few figures which may be of interest to your readers and which conflict somewhat with Mr. Curtis's statement. Concerning their compound condensing pumping engine at Pawtucket, R. I., they say that "taking into calculation *all* the coal used in starting, banking fires and pumping, and no deductions made for ashes or clinkers the consumption of fuel per h. p. hour was 1.66 lbs. for the whole year of 1883."

"A similar engine at Petoconsett which supplies the water for Providence, calculated on the same basis for the same year, was 1.68 lbs."

"Our compound mill engine (tandem) at Nourse Mill, Woonsocket, R. I., gave on a seven days trial on *same basis* 1.62 lbs. of fuel per h. p. hour driving 500 h. p." A. J. NEWELL.

CORRESPONDENCE.

NEW YORK AND VICINITY.

Shall Liberty Light New York Harbor?—Profits of the Gas Companies.—The Lalande-Spence Battery Exhibits.—Plans of the U. S. Signal Bureau.—The Western Union Company Institutes a Libel Suit.—Change in the Firm Name of L. G. Tillotson & Co.—The Southern Joins the Mutual Union Lines.—New Yorkers Visit the Hathaway Printer at Philadelphia.—A New Electric Lighting Station.

THE Bartholdi statue having actually arrived, its erection in the harbor at an early day will afford an excellent opportunity for our western friends to tell what they can do in tower-lighting. As there will be no trees to interfere, according to their theory, New York bay ought to be well lighted by sufficiently powerful lamps placed in Liberty's crown. As the advertisement will be one of the most valuable identified with this great work, second only, perhaps, to that obtained by the eminent sculptor and the enterprising *World*, the bids for the installation will doubtless be very low.

According to published reports, the gas companies are standing up very well under electrical competition. The Mutual leads off with an average net profit for the past year of over $1 per 1,000 feet. The net profits of the other companies per 1,000 feet

Digitized by Google

were as follows: Municipal, $1.02; Knickerbocker, 96c.; Metropolitan, 85c.; Manhattan, 82c.; New York, 72c.; and the Harlem, 45c.

A very interesting exhibition of the Lalande-Spence primary battery is being given at 15 William street, by Mr. Hugh A. Fergusson. This battery has attracted much attention from high scientific authorities in England. It is contained in an iron cell. Against one side is placed an iron grid, the interstices of which are pressed full of oxide of copper. The negative pole is formed of two zinc plates in the centre of the cell, the whole being excited by a single fluid—a solution of caustic soda. The electromotive force is low, as is also the internal resistance of the battery. There is no local action, and the solution, when drawn off, may be treated with carbonic acid gas, precipitating oxide of zinc, a regular article of commerce. This, together with the metallic copper deposited, is said to practically cover the cost of maintenance. Having had no opportunity to verify the statements made in regard to its constancy, we can only say that it is worthy of critical examination. It is the intention to introduce it for domestic electric lighting and motor purposes.

About the 1st of July the U. S. Signal office in this city will introduce a more elaborate system for the display of signals, indicating at all times the latest forecast of the weather. At present flags and lamps are hoisted only in the event of some radical change which is of interest to farmers, mariners and hotel-keepers.

The red flag, with a black centre, is the cautionary storm signal, indicating the approach of at least a 25-mile wind.

A white flag, with a black centre, hoisted above the red, indicates a dangerous "off-shore" wind from the northwest. The same flag hoisted by itself signifies the approach of a cold wave. It is at present somewhat out of practice.

A statement was made in the *Wall Street Daily News* a few weeks since to the effect that the Western Union Telegraph Co. was not earning its dividends. President Green, on behalf of the company, brought suit for libel against Charles D. Keep, editor and proprietor of the *News*. Counsel for the defense intimated that the statement was made in the interest of independent journalism, and that the conflict was inevitable. Notwithstanding all reports of this character, it must be admitted that the Western Union company not only pays its dividends, but its employés and its bills. In fact, it meets all its obligations, and in this respect, at least, has for many years maintained a good financial standing.

The old firm name of L. G. Tillotson & Co., so familiar to all electrical people, is now to be superseded by the title of E. S. Greeley & Co. Practically there will be no change, as the business methods, factories, sales-rooms and offices will remain as heretofore. It will be a long time, however, before the name of Tillotson will be forgotten in connection with the traffic in electrical goods.

The business alliance between the Southern and the Mutual Union Telegraph companies, which was made a month ago, was a very shrewd piece of work. The Southern company's connection was a very important link in the opposition telegraph system, and furnished quite an important share of the Commercial Cable company's traffic.

Quite a delegation of gentlemen from this city visited Philadelphia on June 8th, to inspect the Hathaway printing telegraph system, which has been extensively boomed by the daily press. No name appears of any electrical expert who has yet examined this machine, so that the most that can be learned regarding it is, that some gentleman sat down to a key-board and transmitted despatches with a speed and accuracy that would have astonished the ordinary operator on any of the old systems. Although it was announced that no stock is for sale in this wonderful enterprise, one or two gentlemen in this city have succeeded in getting into the syndicate. It is said that the assets of some of our most conservative capitalists, embrace a fair sprinkling of Keely motor, and similar questionable investments, popularly known on the street as "cats and dogs." Very likely, now that there is a plethora of idle capital, a few individuals may be found who are willing to go it blind in ventures of this description.

The United States Illuminating Co. is constructing a new central station at the foot of 29th street, East river. It is to supersede the 44th street station which must be removed to make way for a new street to be cut through. The new station will utilize 1400 h. p. to be furnished by compound engines, and its capacity will exceed that of the present Stanton street station.

NEW YORK, June 20, 1885.

CHICAGO.

Underground Work in Earnest.—The Streets in a Chaotic Condition.—Satisfactory Experience with the Dorsett Conduit.—Another New Insulating Compound.—How Quotations Have Been Stolen from the Board of Trade.—Western Legislation Against Telephone and Telegraph Interests.—Tales of Bribery and Corruption.—The Great Electric Storm of June 2.—Little Doing in Electric Lighting.

FOR the past few weeks our streets have been in a fearful state of unrest and blockade. The heart of the city has been all "tore up" in the interests of the gas, sewer, water and wire undertakers and sextons. Much the larger portion of the mournful ceremonies have pertained to the work of the underground conduit people, who are literally threading the business part of the city with their conduits for electric light, telegraph and telephone wires. The company which is doing this work is the Chicago Electric Sectional Underground Co., or, as they used to say in patents, "its equivalent, substantially, as hereinbefore set forth." Professor Elisha Gray is the head and president of the company, and the system adopted is that of Mr. D. H. Dorsett, of this city. The material used is a concrete of asphaltum, pressed in sections, containing from seven to 17 longitudinal holes. These sections are molded with a flange at one extremity, so that, on being laid, a joint can be made air, water and gas-tight, by means of the similar material to the body of the conduit, applied hot. By this arrangement the placing of the pipes is readily done, and perfectly finished with a minimum of labor. In talking with the professor, I learned that several of the objections which have been urged against the manufactured material are thoroughly groundless. Neither moisture nor acids have any effect upon the material, and this statement is based upon experiments actually made, for instance, in a mixture of sulphuric acid and water, 50 per cent. of each being used, a block of the concrete was soaked for 30 hours, yet, afterward, with 150 cells of battery and a delicate galvanometer, not a trace of conductivity was shown, and no evidence visible of attack by the acid. It has been assumed also that, from the nature of the compound, it would be liable to breakage by pressure, if, from any cause, the bed upon which it rests were to become uneven from settling, or other causes. An unexpected but very gratifying test of its power to resist crushing strains was made the other day on Dearborn street. A change in the programme of the street authorities altered the grade between two streets, and brought the diagonal pipes, which run from the man-hole to each of the four sections of the block bounded by the street and alley, about four inches above the surface. While these were thus exposed, a street roller was set to work tamping down the substructure of broken stone. Back and forth, crashing over these pipes, that roller went during much of the day, and it was presumed every section would be ruined. Only two joints were loosened out of some 60, and no section was broken. One point more: a section of this conduit which runs to the Grannis block ruins, being about to be used again for electric light wires, was tested a few days since in a rather crucial manner. Naked wires were drawn through two tubes in the conduit for a distance of more than half the square between Washington and Madison. With a battery of 20 cells of chloride of silver, a Wheatstone bridge, and a delicate galvanometer, the insulation proved far above the capacity of the apparatus. Joining the two wires at the farther extremity could not reduce the deflection of the needle.

Another candidate for patronage from wire people has lately come to the front in a novel form. In this system the insulating material—the composition of which is a profound secret for the present—is in a plastic condition, and remains so thus far since the first experiments. It is assumed that it will continue in this condition for years. This material is poured into a wooden box, into which the naked wires are laid, and although these may be within a very short distance of each other, the insulation resistance is shown to be 'way up in the millions. Placing these wires on glass or porcelain insulation to keep the natural sag from making contact at the bottom or sides of the box, will leave them in excellent insulation, and wires can thus be placed underground at a minimum expense, as the material, or "mixture," as the inventor calls it, costs less than any material for such purposes within the knowledge of the writer, is easily obtained, exhaustless and readily compounded.

We have had plenty of amusement hereaway out of the Board of Trade fight with the bucket shops. The former has been puzzled immensely in endeavoring to discover ways and means of preventing the leaks which have been constant during the interim since the quotations were cut off. There is no equivalent for galvanometers in this sort of search, and even shutting out visitors from the open gallery of the board did not stop the waste. The board became desperate, and it was to an extent a matter of self-defense on the part of the members that the guilty party should be caught at all hazards. Many a member, while apparently paying strictest attention to transactions, was in reality watching some suspected individual, in the hope of detecting the guilty party. Weeks of this self-constituted detective work has been going on, but until Saturday last all had gone for naught. On that day one of the officers of the institution discovered, near a window from whence the open board was plainly visible, one whose movements were so uniform as to rivet the attention of the officer. Once on the right track, it required only a little time to get at the whole scheme. At every change in the market, a hand, "right or left, as the case may be," as the old tactics had it, went up to the hat or the cheek. Knowing the interpretation, it is easy to read almost any puzzle. Investigation showed a hole in a curtain at the open board room, but the owner of the eagle eye which had been receiving the surreptitious information saw the commotion which followed the discovery, and disappeared

Digitized by Google

from his hiding place before the board authorities could reach him. It remains to be seen whether this is the last leak, or whether there are other weak spots to ferret out and close up.

Our State Legislature is struggling to put clothes-pins on the noses of the telephone and telegraph companies in the way of regulating them in the matter of taxes and rentals. Up to date the matter has not looked as if it would be reached the present session, as the proposed new election law, in which there is much pro and con of politics, by the way, is the subject of so much wrangling, it is doubtful if these bills, of which there are several, will, any of them, stand much of a chance of becoming a law this year, unless there is an extra session of the Legislature. There has been some entertainment also, arising out of charges of corruption or bribery, or some such merchandising, among the members. A committee of investigation has made a visit to Chicago, but it looks as if they came at an inopportune time. Somehow it happened that the parties whom they desired to interview were out of town. Visiting their mothers, gone a-fishing, or otherwise engaged, so that, like Mrs. Hubbard's dog, they found that—

"When they got there,
The cupboard was bare."

The Ohio Legislature took hold of the matter in a very proper and sensible manner. The bill was placed in the hands of a committee for investigation, who reported it back adversely, having ascertained that the hue and cry about exorbitant rentals did not come from those who pay for telephone service, but from outsiders who have no interest whatever in the question, save from the standpoint of the communist, who believes in a weekly division of this world's goods, provided no one has less than he. In Michigan the bill was strangled by a vote in the House of 43 to 23.

A series of electrical phenomena were visible here on the 2d of June, which were interesting and peculiar. Throughout the early part of the day it was evident from indications that the elements were arranging for a grand fête at the celestial Bois de Bologne, possibly, or a grand display of nature's forces in honor of the near completion of "Brer' Toldi's Liberty frightenin' de worl'," perhaps.

The telephones took up the alarm first, and hissed and sputtered and fried like so many broilers and pans at a fish picnic, or a Friday church festival. The air and the earth seemed charged in every direction. The heavens were coursed by messengers in hot haste, marshaling the hosts of battle and arranging the programme of salutes, distributing the artillery ammunition, and inspecting the ordnance. Towards evening it became apparent that the preliminaries were perfected, and a dead calm succeeded the hurried preparations. Then the curtain—a dense black cloud—rolled up from the west, darkening the heavens as by a bit of stage strategy, to show by contrast the intense illumination to follow. A few preliminary flashes and signal guns, following rapidly as a cue to the wind and rain, were immediately succeeded by a few scattering skirmish drops, a puff of air, and, in less time than is required to chronicle the fact, the rain fell in sheets, accompanied by a terrific wind. Grand salvos of celestial discharges accompanied these, and the entire heavens were illuminated in every direction. The wind, in the course of a few minutes, rose from three to 26 miles per hour, and as suddenly slowed up to a six-mile rate. The temperature also enacted the rôle of star in the exhibition. The mercury fell in 11 minutes after the first burst of the storm, as many degrees. The wind completely boxed the compass. Fifty-four one-hundredths of an inch of water fell in 43 minutes. A peculiarity of the electrical portion of the storm was the persistent discharges in a vertical direction. There seemed to be no evidences of difference of potential save between the earth and clouds. In many instances discharges were repeated in precisely the same line, as far as could be judged, and with no apparent variation of zig-zag deflections, these bolts occurring in several instances in rapid succession—at one time three in as many seconds. To the west these evidently struck the prairie, while to the east the lake was the favored recipient. Within a compass of a few miles around the city, trees and spires were struck, and one or two small conflagrations occurred, but without material damage.

At Highland Park, 23 miles north, the principal hotel was singled out as a mark, and the rod over the cupola received a heavy bolt. Those who chanced to be looking in that direction at the instant witnessed a beautiful exhibition of nature's powers. The entire rod seemed enveloped by an inverted cone of phosphorescent light, which extended downward below the roof of the structure. The charge was partly dissipated through the pipes of the building, and played many harmless freaks in its skipping from point to point, cracking and spitting like minor fireworks in its endeavors to reach the earth. An employé of the house had a cold-chisel ruthlessly snatched from his hand, and thrown across the room.

Within the city we were not so fortunate. Several parties lost their lives from direct bolts, while others in the immediate vicinity felt severe shocks. Two men who were pushing a hand-car in a lumber yard were killed instantly, and, falling, immediately rebounded and turned completely over before striking the earth again. The telegraph people suffered only from the twisting up of their wires—the city wires were comparatively unharmed; but the telephone inspectors had their hands full, exchanging burned for new coils throughout the city, but principally in the southern and southwestern portion of the corporation.

The disturbed elements took a rest after the matinee, which opened about 4:30, and repeated the performance in a milder form during the latter part of the evening.

Lynch & Banta, telephone and telegraph stock-brokers, have dissolved partnership. Colonel Lynch will continue in the same line of business at the office of the late firm, 144 Lasalle street. Colonel Lynch is well known to the electrical fraternity—an operator in the days of telegraphic babyhood, a colonel in the war of the rebellion, detailed for telegraphic duty, secretary of the A. D. T. Co. here; then holding the similar position with the Western Electric Co., he finally went into the business which he is now engaged in, and purposes continuing.

The electric light business is rather dull than otherwise just now, only a few plants going in, and many of these of a temporary or experimental character. It is probable that, by the time you receive the next batch of items from here, something worth while will have developed.

CHICAGO, June 15, 1885.

BOSTON.

New England Weather Prophets to Assist the Signal Bureau.—Economical Tendency of the New England Telephone Co.—Decision in an Electric Gas Lighting Suit.—The Telephone Conference.—Legislative Telegraph Regulation.

THE New England Meteorological Society, of Cambridge, is coöperating with the United States Signal Service for the display of authorized signal flags indicating the weather forecasts made by the service for the New England states. Special indications are prepared at 1 o'clock A. M. each day and telegraphed to Boston and New London for distribution, and by the coöperation of the telephone, time and railroad companies, these telegrams are repeated to all parties authorized to display the official flags in the various towns and country places. Within a short time over 300 different persons in various places have made application to be so authorized. Mr. J. N. Keller, general manager of the New England Telephone and Telegraph Co., has issued an order to the effect that when the weather indications are received at any one of the central exchanges of his company, they will be furnished free, once each day, to one person, to be designated by the Meteorological Society, at any place that can be reached by telephonic communication, and which may be located within the boundary of such central exchange.

The Standard Time and Electric Co., of New Haven, will coöperate with the Southern New England Telephone Co. for the same purpose.

Mr. Davis, the secretary of the New England Meteorological Society, furnishes information to those desiring to become local weather prophets about signal flags, where to obtain them, etc. All correspondence concerning local signals in Connecticut should be addressed to J. H. Sherman, Signal Office, New Haven.

At the present time the Boston exchange sends weather forecasts to Dedham, Canton, Waltham and Medford. This system will be of great benefit to farmers and others interested in agricultural matters, and it is hoped that good parties may be obtained in all places, who will not "get tired" too soon.

The executive committee of the New England Telephone Co. recently held a very important meeting in this city, at which they took the first steps toward the adoption of a more economical policy in the administration of the company's affairs. The action taken will reduce the company's operating expenses over $10,000 per annum, and the other measures now pending will bring them down still further. Among other things, it was voted yesterday to abolish the office of regular attorney, to which a salary of $3,000 per annum is attached. It was voted to abolish the salary of $6,000 per annum paid to vice-president Ingham. The resignation of A. C. Sanborn, superintendent of the Lowell division, was accepted, and it was practically decided not to fill the vacancy. The committee also discussed a plan of reorganization, which will effect a consolidation of all exchanges in the matter of management, and make a large saving in running expenses. The cutting off of many of the employés who can be spared without injury to the company's business, and a general "doubling up" of service, is also among the changes under consideration. The construction work is being kept within the closest possible limits, and it is intended, in short, to do everything that can be done consistently to bring the operating cost down to a basis that will admit of a profit sufficient to give the uneasy and dissatisfied stockholders a good dividend.

Judge Colt, of the United States Circuit Court, on the 20th ult. gave an opinion in the cases of the Boston Electric Co. *v.* the Electric Gas Lighting Co. and the New England Electric Manufacturing Co., sustaining the defendants' plea as to the jurisdiction of the court. The defendant corporations were organized under the laws of Maine, and sued in the Circuit Court for the

Digitized by Google

district of Massachusetts. The writs were served by attachments of corporate property within this state, and by service upon the proper officers here, if such service could be legally made. It was agreed that the defendant corporations have a usual and principal place of business in Boston. The opinion decides that Courts of the United States cannot acquire jurisdiction by an attachment of property merely, but that there must be a personal service of the writ or process upon the defendant, or a voluntary appearance. A corporation, says Judge Colt, cannot be sued in a foreign state, because it carries on business there, in the absence of a state law authorizing such suit. This decision overrules the opinion of Judge Lowell in Hayden *v.* Androscoggin Mills, who held that a foreign trading corporation doing business in the State of Massachusetts may be sued in the Circuit Court by summons duly served upon an officer of the company, the fact of the attachment being immaterial. "We cannot adopt this view," says the opinion, "in the light of what we believe to be the great weight of authority on this question."

The most interesting feature of the month has been the gathering of invited telephone guests at Boston's famous hotel—The Vendome. Including the gentlemen connected with the office of the American Bell Telephone Co., in this city, the total attendance was not far from 75 in all. They literally came from the four points of the compass, and were a fine body of men, representing, as they did, the bone and sinew of the telephone interests in the United States. The proceedings were "strictly private," but the "visiting statesmen" were ready to talk about what had been done, that is, about *most all* that had been said and done. The general business, prospects, etc., as well as practical mechanism, bells, apparatus of all kinds, cables, under and overground, came up for an interchange of opinion and experience. The meeting was formally opened June 8, in the afternoon, being called to order by Col. Forbes, the president of the American Bell Telephone Co., Mr. C. H. Haskins being made chairman, and Mr. E. J. Hall, Jr., secretary. The meetings were interesting and instructive in a high degree, and probably as much solid good information was carried away by each delegate as is usually in the telephone conventions heretofore held. This convention would seem in some measure to forestall the business of the National Telephone Convention, and also a large share of the fun. After the serious business of the delegates had been attended to, an enjoyable visit was made to the elegant offices of the Boston Telephone Exchange, then to Mr. Ezra T. Gilliland's "mechanical department," where the company were shown the new "village telephone system," recently patented and worked out by Mr. Gilliland in his own ingenious and perfect manner. This is an arrangement of apparatus whereby a limited number of subscribers in a small community can call each other and converse without the intervention of an operator or central office. The apparatus is simple and can be easily operated. Many of the telephone men predicted it a success. Carriages were furnished by the American Bell company, and a drive was taken through Boston's superb suburbs, said to be, as are all of Boston's institutions, unrivaled. On Thursday, accompanied by the directors and management of the parent company, a short sail was made in a steamer to Point Shirley, where connection was made with Taft's famous hotel, at which place they sat down to an elegant dinner. The guests are prepared to state that, with all her faults, the "old 'un" knows how to "treat" when her time comes. Friday was passed at the militia muster held in Framingham. Altogether, the affair was a success; the concessions made by the American Bell Telephone Co. to their licensees were announced early in the stage of the proceedings, and were received with satisfaction.

One of the pleasant incidents of the telephone conference, if not *the* pleasant one, was the action taken by the visiting delegates to show their appreciation of the hospitalities shown them. On Saturday morning when the officers and employés of the American Bell Telephone Co. appeared at their offices to perform the daily task, they found their desks and tables covered with beautiful and choice flowers, some in elegant designs, pillows, wreaths, crosses, etc., and the "waste places" made glad with loose flowers, strewn upon the desks. Business could not of course go on under such circumstances, and some time was spent in visiting each others rooms to inspect their several glories. Altogether it was a most delicate and beautiful act, and was much appreciated by the recipients.

The legislature are about through with telegraphic and electric matters of all sorts. In the Senate the following bill to secure greater care in the transmission of telegraphic messages was engrossed, with amendments, to read as follows:—

All persons, associations and corporations engaged in the business of transmitting or receiving telegraphic messages for hire shall be liable and responsible to the amount of $100 in any case for all damages caused by their negligence, or that of their servants or agents, in transmitting, receiving or delivering such messages, notwithstanding any contract, oral or written, to the contrary. No action for the recovery of such damages shall be maintained unless a claim therefor is presented in writing to such person, association or corporation, or to some officer or agent thereof, within 30 days from the time when such right of action accrues. The provisions of this act shall not apply to any negligence occurring in a telegraph office established for the convenience and safety of a railroad corporation in the running of its trains, and transacting a public telegraph business only as incidental thereto.

BOSTON, June 19, 1885.

PHILADELPHIA.

Mayor Smith's Reasons for Vetoing Overhead Line Privileges.—Amendment of the Legislative Underground Bill.—Poles to be Cut Down January 1.—The Firemen Retarded in Their Work by Wires.—Business of the Clay Commercial Telephone Co. at a Standstill.—The "Novelties" Exhibition.—Suit Against the American Rapid.

DURING the early part of this month Mayor Smith sent to Councils the following veto message, which was sustained by Select Council. In the lower branch a new bill was introduced, which meets the Mayor's objections:

GENTLEMEN:—I beg to return, without my approval, "An ordinance granting the Thomson-Houston Electric Light Co. permission to extend its lines by placing poles and wires on Girard avenue, Fairmount avenue, and on Spring Garden street."

The general reasons for the non-approval of the bill are as follows:

Under the ordinance approved June 13, 1882, Councils declared "that it shall be unlawful, on and after January 1, 1885, to erect or maintain any poles and wires for telegraph, telephone or electric light purposes, in the streets of the city of Philadelphia.

While willing to concede that it may not be wise nor reasonable to exact any such far-reaching action, it is beyond doubt, both to the interest of the city and the benefit of her citizens, that due care and precaution be given them in the preservation of their lives and property, and no description of the overhead system of poles and wires is so absolutely dangerous as the system of electric lighting.

Desiring to afford the present corporation an opportunity to avail itself of such privileges as your honorable bodies may deem wise, I would most respectfully suggest the following modification in the ordinance, which will make it more acceptable, namely:

The omission of the service from Second to Sixth streets, upon Girard avenue. A line of wires being already constructed upon each side of the street within this boundary, it can readily be admitted that the existence of another separate and distinct line upon either side of this thoroughfare would be most unwise and obnoxious.

Provision should also be made whereby companies or corporations securing such privileges from the city should be required to furnish city lights at the figures determined upon for compensation for this service, and not avail themselves of a public privilege to exact (as has been attempted by some of the companies) a charge greatly in excess of that paid other equally serviceable and reputable competitors.

Councils have likewise enacted in section 9 of the ordinance of March 30, 1882, "Regulating the introduction and providing for the charges for underground, overground, or overhead wires," that a bond shall be filed of record conditioned that all corporations, firms, or persons will comply with the provisions of this ordinance and of all other ordinances now in force or hereafter to be passed. This company have not been required, nor have they filed any such bond as is contemplated in the ordinance quoted.

Another decided objection to the ordinance is the fact that there is nothing either in the title or body of the ordinance to define or limit the privileges granted. Whilst it may be affirmed that electric lighting is the actual scope and intention of the company, the ordinance is so general, and entirely without any specific utterances of its intentions and desires, as to warrant in asking that its purpose and functions be clearly and plainly defined.

The desire to aid the city in properly policing the property of her citizens, which is much improved and aided by the introduction of an ample and good system of lighting the highways, will warrant my approval of this ordinance, if your honorable bodies may admit, after consideration, the wisdom of some of the suggested modifications; but I must clearly and unequivocally express the belief that, from and after the present time, the executive position will best advance the welfare of our city, and protect and guard the lives of her citizens, and especially those who are officially compelled to brave the dangers incident to fire and its consequent risks, by the disapproval of all future legislation which will add to either the extension or perpetuation of the unsightly and dangerous electric services which incumber our streets.

Very respectfully yours, WM. B. SMITH, *Mayor*.

At Harrisburg, on June 3, the underground wire bill was amended by the committee on corporations to suit the opponents. John R. Read and M. E. Olmstead represented the Western Union Telegraph Co., and T. B. Hughes, of Philadelphia, the Philadelphia telephone interests. An unsuccessful effort was made to strike out the clause prohibiting ground to be broken for the purpose of burying wires from May 15 to October 15. The failure to incorporate this amendment in this bill will render it of very little value, as by ordinance ground is not allowed to be broken in Philadelphia and Pittsburg in December, January and February. The opponents of the bill failed to have inserted a clause for reimbursement for losses sustained in being compelled to bury wires, but they had the following amendments inserted:

That no more than one fourth of the entire plant of any company or city shall be required to be removed or placed underground in one year: that no company shall be required to remove its wires from poles or housetops, or place the same underground in any street in which, or in connection with which, Councils have heretofore passed an ordinance or ordinances giving underground privileges, which are or may be exclusive, until such ordinance or ordinances shall be repealed; that no such ordinance shall be passed which shall not apply to all companies alike, within the municipality, where applicable, which own, control or operate telegraphic, telephone, electric light, or other wires, or a cable, on what are known as telegraph poles.

The bill was reported as amended. Its supporters will probably allow it to pass in its present shape for fear that its amendment might endanger its enactment into law. Its passage, they say, will at least be a recognition of the demand for the burying of wires.

In Common Council, Mr. Vanderslice called up the resolution of Select Council for concurrence, which provided that all telegraph and telephone companies be notified to remove their wires in the district bounded by Vine and South streets and the Delaware and Schuylkill rivers, by the 1st of January, 1886. In case the companies neglect to carry out the provisions of this resolution, the superintendent of the electrical department is to cut the poles and wires. An acrimonious debate ensued upon the resolution, and an attempt was made to recommit it. This was defeated

Digitized by Google

by a vote of nine yeas to 48 nays. The resolution was then adopted by a *viva voce* vote. It had previously been adopted by Select Council.

In his report to the board of fire commissioners, the other day, chief-engineer Cantlin took occasion to refer to the recent destructive fire at the southwest corner of Second and Market streets. He said the greatest drawback experienced by the firemen in fighting the flames was the network of telegraph wires on both sides of the building. These prevented the use of the ladders in the early stage of the fire. The poor wires are catching it from all directions, but it will be a rather expensive funeral when the time comes to bury them.

Pending the judge's decision in the Bell Telephone suit against the Clay Commercial company for infringement of patents, the latter company's business is at a standstill. The case has been argued pro and con, but the judges seem in no particular haste to decide the matter. Meantime the Clay Commercial keep their main office open, but I understand that all hands connected with the concern might as well commence to take their summer vacations, and it is quite likely that they will be able to extend them far into the winter.

Rules have been formulated for the Novelties exhibition, to be held in the fall, under the direction of the Franklin Institute. The building at Thirty-second and Lancaster avenue will be opened for the reception of exhibits on Monday, August 24, and continue open for that purpose until Saturday, September 12. On Tuesday, September 15, the exhibition will be formally opened to the public, at 12 o'clock M., and continue open daily (Sunday excepted) from 10 A. M. to 10 P. M., until Saturday, October 31, 1885.

The case of Wm. B. Gill & Co. against The American Rapid Telegraph Co., of Connecticut, brought to recover $12,447.43 and interest, for work claimed to have been performed in constructing a telegraph line from Philadelphia to Pittsburg, resulted in a voluntary nonsuit yesterday.

PHILADELPHIA, June 17, 1885.

WASHINGTON.

Effectual Injunctions Against Pole Lines.—Wire Legislation Becoming Obnoxiously Effective.—The Washington Monument a Target for Lightning.—Taking in the Southern Telegraph Co.—Wires to be Cut Off the Treasury and White House, July 1.—The Legal Rights of the Small Boy.

LEGAL proceedings have been the feature in electrical matters here during the current month. In my last I mentioned that the Western Union company was replacing its air lines in the central part of the city with a pump-log cable line and thence through Seventh street to the boundary by a heavy pole line. When they had about half finished the laying of the pump-logs to receive the cable and had made equal progress with the pole line, certain citizens along the latter route sought and obtained an injunction restraining the company from erecting their poles and ordering those already up to be removed. Judge Hagner who heard the case, was once president of a telegraph company with a 20 mile line between Annapolis and Annapolis junction, and is therefore an expert on electrical matters. He declares there are no obstacles in the way of underground wires. This settles the matter notwithstanding the opinion of Judge Black, of Pennsylvania, in a similar case, he holding that the question had not passed the stage of experiment. But then Judge Black had not manipulated 20 miles of wire. Judge Hagner further held that the district commissioners had not been given such control of the streets as would warrant them in surrendering any part of their use to private individuals or corporations. The case was appealed to the court in *banc* to be heard by all the judges, at some time in the indefinite future. Meanwhile the pump-logs as far as laid await the cables and the Western Union sends its messages over the 10 or 12 miles of poles in the heart of the city, that would have come down had the mile or less on Seventh street, been constructed. The Telephone company is doing a large amount of underground work. To reach their patrons they put up a pole in the alley as near the centre of each square as possible. To this they run their cable and enter the buildings by the rear by air lines from the alley poles. But even they are met with suits for injunctions—which, if Judge Hagner's decision stands, must be granted. In their case the difficulty can be met for there will always be some one with public spirit enough, to permit the single pole required for his square to be put up on his own premises. But another question comes up. If the commissioners cannot grant authority to put up air lines where is their power to have the carriage-ways, side-walks, parking, etc., torn up to lay the necessary conduits? May not any citizen whose place is passed sue out an injunction?

The United States Electric Light Co. whose proposed expansion has hitherto been mentioned, had secured a site in Georgetown with extensive water-power; obtained permission to run their wires partly above and partly underground, arranged for the necessary funds by the issue of bonds and were all ready for a very material enlargement of their plant, when confronted with the action of the Court. As a consequence they are at a standstill. All negotiations have been stopped, and they will continue business at the old stand to the extent of their present capacity. Should the Court in general term sustain Judge Hagner, it makes all permits heretofore issued for poles void, and Congress will have to legislate upon the subject.

The daily press has had numerous notices of the Washington Monument being struck by lightning, until a portion of the capstone was split off, necessitating the restoration of the scaffolding to bolt on the fractured piece. While this was in progress, tests were made of the resistance of the conductor, and it was shown to be $2\frac{1}{10}$ ohms. The aluminum tip was found badly battered. This tip is connected by a copper rod through the cap-stone with the heavy wrought-iron work that supports the elevator, and the bottom of this iron work is supposed to be connected with a well below the concrete base of the shaft. Where this resistance comes in has not been explained. From the published daily reports it would appear that those in charge are seeking to increase the facilities for collecting electricity rather than providing better means for its discharge into the ground.

A short time since, by the light of the moon, the wires of the Southern Telegraph Co. which connected with the Bankers and Merchants' line, were cut and quietly connected with wires leading into the office of the Western Union company, and the Southern is made a part of the Mutual Union *alias* of the giant monopoly. Efforts had previously been made for a connection with the Baltimore and Ohio system, but the terms offered by the latter were not deemed sufficiently liberal to warrant the connection, and so the Southern goes the same way as hundreds of like local lines have gone before. The Bankers and Merchants' and the Postal bid fair to be no exceptions to the rule, and when they reach a certain stage may follow all their predecessors. Experience seems to have no effect in deterring people from embarking in small telegraph enterprises, and if these lines should be "gobbled" by the Western Union, new lines would probably be started over the same route on which the House, Bain, Independent, Insulated, Franklin, Bankers and Brokers', Commercial, and a half dozen others, perished.

Col. Wilson, the new commissioner of public buildings and grounds, is getting restless under the delay in removing the wires from the treasury building and executive mansion, and has notified the companies interested that if they are on the 1st proximo he will have them cut down. As there seems to be no authority anywhere to give permission to put up poles or to lay cables, the companies are in a quandary, and are waiting for "something to turn up."

A day or two since a police officer arrested four small boys for climbing telegraph poles in the street to get a sight of Buffalo Bill's Indians, who were giving their wild western exhibition in Athletic park. The lads were brought before the police judge, who decided there was neither trespass nor disorderly conduct on the part of the boys, and dismissed the case. The youngsters evidently read the papers, for they now climb the poles around the base ball grounds, and the police have to content themselves with driving the smaller ones away from the knot-holes in the high board fence, on the plea that they trespass upon the parking between the sidewalk and fence.

WASHINGTON, June 24, 1885.

WILLIAMSPORT, PENN.

The Edison Lighting System.—Abandonment of Meters.—Proposal for Street Lighting.—The Telephone Business.—Adoption of Hard-drawn Copper Wire.—Systematic Inspection of Lines and Equipments.

ALTHOUGH a city of but 25,000 inhabitants, Williamsport has shown great interest in electric matters. In order to establish an electric lighting system $100,000 was raised for the erection of an Edison central lighting station of the most approved and substantial form. It is a large brick building equipped with two 180 h. p. and one 140 h. p. Buckeye engines, and 4 large steel boilers equal to 500 h. p. The engines were set up with the greatest care running the dynamos direct, and it is spoken of as the model central station in this country. There are nearly 4,000 10-candle-power lamps which are furnished at about the same price as gas at $2,00 per 1,000 ft. The new station was started Oct. 1884, and has been increasing gradually ever since.

The meter system was abandoned, and special contracts made shortly after the station was started. The lines are all well and substantially built all overhead, or pole lines. The plant has a capacity of about 8,000 lamps which number no doubt will be subscribed for in due time. The company has made a proposition to the city council for the street illumination, which is to be awarded soon.

This is the headquarters of the Central Penn'a Telephone and Supply Co. Williamsport was among the first cities in the state to adopt the telephone, the exchange being open in April, 1879. Williamsport and Wilkesbarre, each with about the same number of subscribers (425), have been equipped with the multiple switch

Digitized by Google

boards. Scranton, Pa., the largest exchange of the company, having about 550 subscribers, was furnished with the same switch board about a year ago. All the smaller exchanges have been equipped within the past two years with the most improved Western electric switches and the lines erected, especially the extra-territorial, are fully up to Western Union standard. For a number of the lines No. 12 hard-drawn copper wire has been used. The company will erect about 100 miles of this wire this season to replace some of the more busy iron lines, that better service may be given. The line connecting Wilkesbarre and Scranton exchanges (a No. 9 iron wire) has been duplicated by a No. 12 copper line on an independent set of poles and by a different route, to accommodate the increased business, between these points. By these lines no difficulty is experienced in talking 100 miles, the annunciator drops in switch boards, all being shunted. Great care is taken to provide the highest standard of service throughout the entire territory of this company, the most improved machinery, and close inspection of lines, instruments, etc., being required.

WILLIAMSPORT, Penn., June 25, 1885.

ELECTRICAL NEWS AND NOTES.

PRESENTATION OF THE HENRY MEMORIAL TABLET.

ADDRESS OF EDWARD N. DICKERSON, ESQ.

Alumni day at Princeton, June 16, was the date selected for the presentation to the college of the memorial tablet, the gift of several friends of the late Professor Joseph Henry. The tablet has been placed in Marquand chapel. It is of marble with a medallion bust of Professor Henry in the centre. Edward N. Dickerson, Esq., of this city was invited to deliver the presentation address, which was not only an eloquent tribute to the memory of the great scientist, but is of special interest as showing the importance of his discoveries in their relation to the telegraph system as it exists to-day. At the request of the college officers, the address is being published in pamphlet form, from the advance sheets of which we are enabled to present it in full.

Mr. President and Gentlemen, Trustees of the College of New Jersey:

The pleasing but sad duty has been assigned to me of presenting to you this memorial tablet of the beloved master, who once shed the lustre of his genius over this ancient seat of learning, and once attracted to its classic shades, allured by his great reputation, pilgrims from all lands, to drink from the living font of knowledge, ever replenished and refreshed by his ceaseless contributions.

I commit this monument to your tender care May it ever remain enshrined in this beautiful temple. May its presence encourage those, and the successors of those, to whom he delivered his torch of science, ablaze with a light which had penetrated to the farthest ends of the earth, to tend that sacred flame, so that when they shall transmit it to their successors, it shall still be borne high aloft in the upper atmosphere of pure truth, with still increasing lustre—a guiding beacon to the wayfarer, wandering and astray in the gloomy valleys of ignorance ; those deep defiles, where the shadows seem ever darkening by contrast with the brightening mountain tops illumined by the rising sun of knowledge.

May it inspire the ingenuous youth, who in the thronging years of the future shall gather about these altars, to search the character and achievements of the great master ; that they may be taught by him how to study ; how to think ; how to work ; how to live ; and how to die.

May it continue to remind those who annually are attracted here to witness the evidences of the growth of knowledge, as they are exhibited in the commencement seasons, that once this college was honored by the ministrations of Joseph Henry, an American, who, with means created almost wholly by himself, rivaled the achievements of the greatest scientists of the old world, working with the resources of nobly endowed institutions, and encouraged by the bounty of kings ; and for years was ever a leader in the vigorous attack upon the arcana of nature, made by the champions of science in the early years of this century.

For those of us who enjoyed the happiness of knowing him well, and loving him dearly, no sculptured marble is needed to stir our hearts, or to keep fresh in our memories that noble presence, which at once charmed and satisfied our senses. Nor, if the chisel of the artist were guided by the genius that once inspired Phidias, would it be capable of fixing upon dull, cold marble, more than one of the almost infinite variety of expressions revealing to the world without, the exalted being within.

But to those who have never seen him, or having seen him have never known him, and to those who shall come after us, it will be something to look upon this marble, and inspired by the thoughts he uttered, and the deeds he did, contemplate its calm expression, and imagine what must have been the living man.

In the year 1839, nearly half a century ago, brought here as a student, I first saw Professor Henry. I remember it well—the time, the place, and the surroundings. Boyish imagination had pictured the great discoverer as a venerable man, bowed down with the toil of years, bearing the furrows, with which overtasked nature revenges herself, traced upon his brow—such a person, perhaps, as the artist has presented to us in the familiar picture of Humboldt in his library.

How different the reality ! In the maturity of a perfect manhood he stood :

> " A combination, and a form indeed,
> Where every god did seem to set his seal,
> To give the world assurance of a man."

His clear and delicate complexion, flushed with perfect health, bloomed with hues that maidenhood might envy. Upon his splendid front, neither time nor corroding care, nor blear eyed envy, had written a wrinkle, or left a cloud ; it was fair and pure as monumental alabaster. His erect and noble form, firmly and gracefully poised, would have afforded to an artist an ideal model for an Apollo. The joy of conflict and of triumph beamed from his countenance—a conflict in which, for years, he had struggled with the phantoms that guard the hidden treasures of nature, and had ever been victorious. And above all, surmounting all, infinite charity and gentleness—like the charity and gentleness of a loving mother for her erring children.

To him the youthful student bowed down in profound admiration. To him, and to his memory, for nearly fifty years he has clung with ever-increasing love and affection. And now that seven years have passed away since death severed the bond, strengthened by a life-time of intimacy, he recurs with fondest memories to the many happy occasions when it was his good fortune to spend hours in sweet and instructive converse with this gifted mortal, to whom the whole book of nature was an open volume, out of which he ever read lessons of wisdom, and beauty, and truth.

As Professor Henry appeared in 1839, so he continued till 1847, with but little change in the physical man—only that change, which, like the changes in the early autumn, lightly touched with tints of exquisite beauty the mature growth of springtime and summer ; and then, with extreme reluctance, he departed from Princeton, called by his country to lay down the arms with which, as a soldier in the ranks, he had been waging his warfare against ignorance, and to take command of the intellectual forces to be summoned and organized by him in the same glorious cause.

Born in the dying moments of the eighteenth century, his age was marked by the numbers denoting the years of the nineteenth. But, like the century, with whose growth his growth kept pace, he had developed with almost unexampled rapidity ; and at the age of thirty-two, wheh he took his chair here, although " he was but a youth, and ruddy, and of a fair countenance," and was armed only with a simple sling of his own construction, and pebbles from the brook of nature, he was equal to the trained warriors of maturer growth and superior armor, waging battle against the Goliah that guarded the unexplored regions of nature's secrets ; and like the great king of Israel, after the brunt of the battle was over, he came to be a leader of the hosts, who once had been tending only a " few sheep in the wilderness."

Let us contemplate for a moment the intellectual stature of our departed teacher, considered merely as an investigator of natural laws, and measured by the standard established by the intellectual world

It is in the order of nature that the intermittent progress of humanity is made under the guidance of gifted men, appearing from time to time, who push forward the outposts of truth, whether in morals or physics, calling upon their fellow men to hasten and occupy the newly-conquered fields. The names of such men are few, and are written upon the rolls of fame. Their glory belongs to no nation, but to all mankind. Sometimes simultaneously and in different parts of the world two such appear, who seem to have been cast in similar moulds, lest perchance one might die or fail, and progress stand still. Such men were Henry and Faraday, whose intellects were molded with the same capacities, and who worked out their tasks in the same spirit. If either one had died before his work was done, the other was capable of doing it : and, in fact, both in many cases struck out the truth, each unconscious that the twin thought had been born in the brain of the other.

To those devoted friends and admirers of Faraday, who delight in singing his well-earned praises, and who best comprehend his achievements, it seems that his discovery that electricity might be produced from magnetism, was his grandest result. Upon it depends many of the most important applications of electricity to the uses of man ; and in the near future many more are coming. Tyndall, the successor of Faraday, does not restrain his enthusiasm when he contemplates this achievement. " I cannot help thinking," says he, " while I dwell upon them, that this discovery of magneto-electricity is the greatest experimental result ever obtained by an investigator. It is the Mont Blanc of Faraday's own achievements. He always worked at great elevations, but higher than this he never subsequently attained."

Digitized by Google

Let us accept the standard, and apply it to Henry; let the achievement measure the power of the man.

In November, 1831, Faraday read before the Royal Society his memorable paper "On the Evolution of Electricity from Magnetism," illustrated by drawings of the apparatus, in which figure 1 is the *compound* "spool," discovered by Henry in 1828, and which Faraday used in making his discovery. No publication referring to this paper had reached this country till April, 1832, when a vague reference, made to it in the *Annals of Philosophy*, was seen by Henry, which led to his publication of July, in *Silliman's Journal*, where he gave a full account of this great discovery, made by himself before he heard of Faraday's work, which, when compared with Faraday's paper of November, exhibits Faraday's experiment for solving the problem. When he wrote his paper, Henry, misled by the imperfect statement in the *Annals of Philosophy*, supposed that his experiment had differed from Faraday's, but was undeceived when the full publication reached him. In 1831, a teacher in the Albany academy was very remote from London and the Royal Society.

In that same year, and in the same few weeks, Faraday first, and Henry after him, independently made the discovery of magneto-electricity; "the greatest experimental result ever obtained by an investigator," in the opinion of Tyndall.

In the same field, and during the same years, were the other great scientists of the world studying the same subject: Ampère, Arago, Oersted, Davy and a host of others; but these two did it, and not the others; and Henry did it by devices of his own invention, unaided by anything which Faraday had discovered or produced, while Faraday used Henry's electro-magnet in performing his most important experiment.

The towering heights which were scaled by the daring spirit of Faraday from the east were at the same time surmounted from the west by our own countryman. Both were climbing from opposite sides at the same time, and neither was conscious of the other's efforts till both stood, face to face, upon the summit. Had Henry been furnished with the corps of trained mountain guides and Alpine stocks, such as attended Faraday in his ascent, perhaps *his* foot would have first trodden the peak, and Prof. Tyndall's song of triumph have been addressed to him.

But when we compare Henry with Faraday, who is the acknowledged unit of comparison, the accidental conditions under which both existed and worked must be known, or justice cannot be done. Electrical science was the field to which both spontaneously directed their studies. Its mysteries at once excited curiosity and baffled research. Its most obvious phenomena had only for a short time been recognized, and everything was to be learned. What they did in that science not only constitutes the greater part of their claims to reputation as investigators, but is almost the whole of our present knowledge of magneto-electricity.

But how superior in every respect, except in God-given intellect, was the equipment of Faraday! He was eight years older than his rival. In the year 1813 he was appointed assistant in the laboratory of the Royal Institute, under Sir Humphrey Davy, then one of the foremost scientists of the world, who, attracted by Faraday's genius, was directing his studies and forming his mind. At that time Henry was but 13 years old.

In the next 12 years Faraday was at work, with all the resources of the Royal Institute, under the instruction of the great Davy, in acquiring the knowledge with which he was armed when he began his original investigations; while Henry, during that same period, was struggling unaided for such education as might be obtained from the scanty resources of a country town; and with that proud independence, ever so marked a feature of his character, was supporting himself by teaching to others a part of that which he was learning himself.

In 1825, Faraday had so improved his great opportunities, that at the age of 34 he was appointed "director of the laboratory" of the Royal Institute, where everything that science could suggest and money procure was at his command in aid of research. Henry was then a private tutor in a distinguished family at Albany, studying mathematics in hours when his duties to his pupils had ceased, and when other young men might have thought they had earned the right to relaxation and enjoyment.

In 1824, before Henry ever had in his hands any instruments for research in electricity, Faraday, thus trained and equipped, began his attack upon the problem of magneto-electricity and failed; and in 1830 it was not yet solved.

The discoveries of deductive science need no apparatus. They are made and matured in the brain; and to record them is the only physical incident to their existence or development. Plato would have looked with disgust and contempt upon a laboratory, and would have scorned the suggestion that time, or place, or physical surroundings, could affect the workings of his mind, or influence his deductions. But the new philosophy, which has changed the face of the world, is of no such ethereal nature. It is born in observation of physical things; it is nurtured upon experiments that cost money, and time, and labor; its maturity is in perfected arts and in things to be seen, and handled, and enjoyed by the senses; its end is to subordinate the blind forces of nature to the uses of man—to mitigate the ills and multiply the joys of life. Those who are the servants of this philosophy must be provided with materials with which to reproduce, in miniature, the conditions that exist in nature in grander proportions, or they cannot ask the questions whose answers they are seeking; and, other things being equal, he, who is well provided with all these needful things has an immense advantage over another who lacks them.

For 13 years Faraday had been pursuing his investigations amply supplied, and was in the full career of successful experiment, when, in 1826, his great rival first looked upon the course over which he was to run, and even then Henry had to depend upon the meagre facilities of the Albany academy, and the voluntary assistance of an appreciative physician, Dr. Philip Ten Eyck, of Albany—a name to be held in grateful remembrance by all who feel a pride in the achievements of the great scientist, whose early efforts were assisted, and whose hopes encouraged, by this enlightened friend.

With such a beginning as this, who could expect that the young aspirant for fame should ever overtake his great leader in the friendly contest? And when he did overtake him, and in some important investigations surpass him, who shall deny that Henry, as a physical investigator, was the equal of him above whom it is conceded no other man has risen in this century?

In still further pursuing his researches into the subtle phenomena of electricity, Henry made, here in Princeton, another capital discovery, this time in advance of Faraday, which forms an important element in the science of electricity. It is to be found detailed in any school-book, under the name of "Henry's coils." His wonderfully elaborate investigations will be remembered by the students of that day, as they were conducted in part in the open air. Wires stretched across the campus, in front and in rear of Nassau Hall, were the means by which the questioner was cross-examining nature, and wresting from her reluctant grasp her hidden secrets. At that time telegraph wires did not exist, and those fine lines traced across the sky excited the liveliest interest in the students, whose fantastic guesses as to their significance were the cause of much pleasantry in the idle hours.

In the course of these investigations it was also the good fortune of our scientist to first discover the very curious phenomenon of "self induction," as it is now called, which plays so important a part in the creation and use of electric currents on wires, sometimes injuriously and sometimes beneficially. Without the knowledge of its laws no duplex or quadruplex telegraph could be practically operated; with that knowledge it can be neutralized when it is injurious, and made available when useful. The brilliant spark which follows the pulling of the pendant, attached to an electric lighter for inflaming a gas jet, now in common use, is one of the valuable practical applications of this principle so discovered.

In contemplating the discoveries of the scientist, there are two aspects in which they present themselves. In one view we consider merely the difficulty of the achievement; in the other, the value of the result to mankind. The first view is obvious when the thing is done; the other is to be reserved for a future day, when all the consequences have followed the original cause. The first view is that which measures the power of the man, just as the lifting of a huge weight by some Hercules exhibits his strength, even though the thing done may be, or may seem to be, useless. The capital discoveries I have named, made by Henry and Faraday, exhibited the giant's strength when they were made, and measured the men who made them. They were found at great depths below the surface, where mental vision can only penetrate by the aid of lenses constructed *in advance, in accordance with the very laws for whose discovery they are needed*—creations of the scientific imagination, and called scientific hypotheses. In such creations Professor Henry was excelled by no man.

Time will not permit even a hasty review of all the scientific labor done by Professor Henry at Princeton, during those years when his chief duties were instruction, and when he had only a portion of his time in which to work for mankind and for reputation; and I must be content with a passing glance at a part of it.

Among those wires which were strung across the campus in 1835 was one used for a magnetic telegraph between the professor's home and his laboratory in the Philosophic hall; and that telegraph line was the first in the world in which the galvanic circuit was completed through the earth—one end of the single wire-circuit terminating in the well at the house, and the other in the earth at the hall. Steinheil, in Munich, in 1837, worked his electric telegraph in the same way by a single line wire, using the earth as part of the circuit, over much longer distances; but it was first done in this campus.

Nearly a century earlier our great countryman, Franklin, had drawn from a surcharged thunder-cloud, upon the string of a kite, in a pouring shower of rain, the lightning of heaven, and had demonstrated its identity with the puny spark of an electrical machine; and with that capital experiment his fame is more closely associated than with any other of the great truths he discovered. In these grounds that experiment was amplified, and still further results obtained, by the man for whom the mantle of Franklin had been waiting all those years, and who was the only

Digitized by Google

American whose stature would not have been dwarfed by assuming it.

From the clear, blue sky, with two kites, one above and assisting the other, held by a delicate wire wound on an insulated reel, Professor Henry drew down streams of brilliant sparks, intensified by the self induction of the wire itself ; thus proving the electrical relations of the earth and its envelope. So, a child's plaything in the hands of a master, reveals the hidden mysteries of the universe.

Away beyond the distant horizon we see at times a quivering illumination of the sky, but hear no thunder. How shall that phenomenon be questioned? Fifty years ago, Henry converted the metallic roof of his house into a great inductive plate, by soldering to it a copper wire, and leading that through an electro-magnetic coil to the ground ; and with that he held converse with the distant lightning, so far away that its voice could not be heard. If the gods of mythology, who hurl their thunderbolts, have a system in their signals, this apparatus would enable us to read their thoughts. Within a few months, a device has been put into operation by which telegraphic communication is kept up between the running cars on railroads and the stations, so that the positions of all the trains may at any time be known, and protection against collisions assured. To do this the metallic roof of the car is used as an inductive plate, just as was the house roof 50 years ago ; and a wire passes from it through a signaling coil to the ground by way of the metal wheels and track. Near the roof, outside, an electric wire is stretched on poles, through which electric flashes, like lightning, are sent, and they set up by induction in the roof electric currents similar to those passing over the wire, which are read as signals by the observer ; and, conversely, signals are sent from the roof to the wire by induction coils in the car. The experimental demonstration in Princeton has not been lost, though buried so long, and to day it throws another safeguard around our lives.

The first electro-magnetic engine for generating power was made by Henry, at Albany, in 1831. His clear mind was not deluded into the belief that such an apparatus could supersede the steam engine as an economical motor, and he warned the world against that delusion. Zinc, as fuel in a battery, is more costly than coal in a furnace. Still, he saw and said that in exceptional cases it might be useful ; a result now coming to pass, dependent, however, upon the discovery of magneto-electricity by which galvanic batteries are dispensed with, and electricity, made in quantities from some great and economical source of power, is distributed to Henry's machines wherever they may be.

In many volumes, some of which have perished by fire, and some remain, were laid out lines and plans of investigation by Professor Henry, needing only leisure and means for their development, covering fields where other investigators have since reaped rich harvests of fame, but from which he was debarred by the pressure of his other occupations here. In those records are contained the evidence that the great intellect, which did so much with so little, was capable of grasping the whole circle of physical science, and of enriching and adorning any department of it to which his efforts might be directed.

But he was destined for another career. A benevolent Englishman, inspired by the noble ambition to aid in elevating mankind, had bequeathed to the United States a great sum of money to be used for "the increase and diffusion of knowledge among men." It was a splendid gift, and a sacred trust. Who was to be found equal to the task of effecting this grand purpose? The civilized world was interested in that question. Mankind was the beneficiary of the trust; and all men were entitled to be considered in its administration. By the common consent of the wisest and best of Europe and America, Professor Henry of Princeton college was selected, and solicited to assume that onerous duty. What tribute was that to the achievements, the attainments, and the character of the man? He must be famous, that his selection might at once command the assent of the world; he must be learned, that he might be able to carry out the purposes of the donor; and he must be virtuous, that he should not degrade the high office to any base or selfish uses. And thus he was called.

When brought to the parting of the roads, choice was extremely difficult. On the one hand, a life devoted to the most delightful of all pursuits—the searching out of the laws of nature, which are the thoughts of God ; a reputation already great and daily growing ; and a happy home, surrounded by congenial and loving friends, and undisturbed by cares for the present or the future. On the other hand, an abandonment of the field of scientific research, where the harvest was abundant, and the laborers few; and a surrender to others of the prizes which he saw glittering before him in the race he was running; and furthermore a grapple with the problems of organization and finance, and with the discordant elements which the scheme of the Smithsonian institution would necessarily evoke. He foresaw that he *might* find himself, after some years had passed, like a giant shorn of his strength ; on the one side outrun in the race where he had ever been in the lead ; and on the other so hampered and crippled as to be unable to accomplish the great objects for which alone he was about to abandon his first love. That high sense of duty which governed him in every act of his life decided the question, notwithstanding his firm conviction that in accepting the trust he left the happiest days of his life in the past.

Perhaps he might have decided otherwise if Princeton college had been then as it is now. Perhaps he then might have felt, that with such ample resources at his command as are now to be found here, his services to humanity might be greater as a soldier in the ranks than as a commander in the field. But at that time no one had arisen among the friends of this institution who, like the Medici of the fifteenth century, was able at the same time to gather the wealth of the world by the arts of honorable commerce, and to appreciate that the gathered wealth of the world owes its existence and preservation to science, to art, and to literature ; and that, therefore, it is due to education that it should be encouraged by noble gifts, such as have enlarged the capacity of the college of New Jersey, and reflected honor upon the names of those whose generous hearts, guided by wisdom, have lead them to broaden these ancient foundations, and to arm with improved facilities the workers who are here devoting their lives to the advancement of knowledge. All honor to such men. Had such assistance come earlier, the career of the great scientist might have been different; but it was not to be, and thenceforth another life opened before him, and another man was unfolded to the world.

Perhaps the highest praise that can be bestowed upon any man, is to say of him that he is just equal to all the duties ever imposed upon him, and never above them; that his reserves are not called into action until the emergency requires them. Such men are the great benefactors of mankind. Such a man was the secretary of the Smithsonian Institution. The principles he laid down for the administration of the noble gift of Smithson required time for their development, and promised no present brilliant results. The foundations were to be laid deep in the earth, where the laborer and his work were scarcely to be seen by the passer-by. No popular applause would greet the achievement for years to come, while popular clamor was ever ready to cry out against the waste of time and money that produced no instant fruits. The man of clear purpose and resolute will, stood guard over the work ; and with just force enough, and no more, drove off the assailants till the foundations were all secure, the superstructure begun, and it was strong enough to stand alone.

With the skill that would have adorned a professional diplomatist, he temporized and compromised, when he could no longer contend with success ; with the dash that would have illustrated a general, he attacked when the moment was propitious, and the adversary off his guard. With the earnestness of sincere conviction, and with the directness of demonstration with which his scientific training had armed him, he convinced, one by one those who opposed his views, until at last the regents of the institution, and Congress, surrendered their judgments to his, and the field was won.

A great library was the dream of Mr. Choate, the most scholarly and persuasive of advocates ; and as a regent, he possessed and wielded a formidable power. It was hard to persuade him that a library does not "*increase* knowledge among men," and that it was very likely to "*diffuse*" ignorance. To discover and accumulate new truths, and to diffuse them over the whole earth, was the secretary's conception of the donor's intention ; to pile up in Washington a miscellaneous collection in print of *old* truths and *old* errors, was the idea of the scholars; and they were so strong that a temporary compromise was necessary. The vigorous growth of the true conception at last overshadowed the false one, and the library no longer saps the life of the institution. Professor Henry always thought that over every library portal should be written some such warning as "*cave canem*"—beware of the lies.

It was not till 1852 that the serious attacks upon the Smithsonian came to an end. On the 24th of June, of that year, a United States agricultural convention, met in the theatre of the Smithsonian building. The plan to plunder the institution seems to have been carefully considered and matured; and the officers of the Smithsonian were elected members of the convention. Stephen A. Douglas was at that time at the height of his power. He had risen from the ranks by the arts of the politician, and was the most influential man in the Democratic party of that day. Although not yet forty years old, he had just succeeded in defeating General Cass in a contest for the presidential nomination at Baltimore ; and although he failed by a few votes to secure it, he had thrown it to Franklin Pierce of New Hampshire, and thus kept it open for himself in 1856, as the western candidate of the party.

He was styled the "little giant"—not in derision, but in admiration, as expressing the combination of a small stature and great intellect. Representing in the convention what was then an almost entirely agricultural constituency, he thought that votes were to be got, and his influence strengthened, if he could bring home to them the spoils of the Smithsonian ; and accordingly a resolution was introduced petitioning Congress to appropriate a portion of the Smithsonian money for an agricultural bureau ; and Judge Douglas undertook the congenial task of accomplishing the raid. The recollections of that battle are

Digitized by Google

among the valued treasures of memory, associated in my mind with Joseph Henry. In such an assemblage, and with such a cause, Douglas was an adversary to be feared by any man. That he was an accomplished politician was proved by his great success; and he was there to fix another step in the ladder by which he had climbed so high. His speech was adroit, as only he could make it. Its argument was founded upon the proposition that civilized man depends upon agriculture, without which barbarism would sweep over the land; and his conclusion was that the farmer was entitled to whatever assistance could be got out of the money of Smithson, whose benevolence could best be applied in encouraging those who were at the very foundations of civilization. It would be great injustice to Judge Douglas to assume that he supposed the diffusion of papers of turnip seed among farmers was that sort of "increase and diffusion of knowledge among men" designed by Mr. Smithson; but no doubt it would be an increase and diffusion of the knowledge that he was the friend of the farmer, and that was of more importance to him. The secretary, surrounded by a few earnest friends, and prepared for the assault, sat in the back seat of the theatre quite unnoticed, kindling with righteous indignation at this nefarious plot to confiscate the funds of which he was the chosen guardian, and to destroy the institution devised by his intellect, reared by his unceasing efforts, and guarded so far by his sleepless vigilance.

When the popular applause following the "little giant's" popular speech had subsided, the secretary arose. In measured and dignified words he presented himself as the guardian of that fund, bound so far as in him lay, to defend it from spoliation. He first developed the moral aspects of the question, and appealed, over the head of the advocate, to the honesty of the constituents he represented; expressing the most generous confidence that the farmers of this country would never consciously be parties in an attempt to seize that which belonged to mankind in general, or seek by a forcible partition to destroy the unity and efficiency of the fund.

The legal aspect of the question he next discussed like an equity lawyer, and denounced in scornful sentences that attempted breach of trust which was implied in the resolution.

And then, out of the fullness of his knowledge, with abundance of illustration and example, he demonstrated that the discovery of new truths, and their application to the arts, had elevated the farmers from the mere drudges they were in the seventeenth century to their present high state of intelligence and comfort.

The effect was overwhelming; and the "little giant" must have felt that there was another giant there to whose title no diminutive prefix could be properly applied.

The meeting adjourned till the next day, and these significant words were written in the secretary's diary, under date of June 25: "Judge Douglas, toward the close, made an apology for the warmth of his expressions. I did the same. Judge Rusk followed—so the whole was amicably settled."

Since that day no further assaults have been made on the Smithsonian Institution; and it stands a proud monument to the genius, the learning, the labor, and the character of the great secretary; who was content to sink his personality in the impersonal institution—to be overshadowed by the creature of his own creation, in order that true knowledge might the better be increased and diffused among men.

The conscientious obligation he felt pressing upon him to lose no opportunity for diffusing knowledge and correcting error, imposed a vast amount of unrecognized and unrequited labor. The intellectually halt, and lame, and blind, continually resorted to him for help, either in person or by letter; and they never were sent away empty. Like the home of the lovely country parson in the Deserted Village:

> "His house was known to all the vagrant train;
> He chid their wanderings, but relieved their pain."

They who have witnessed some of those deeds of charity, will never forget the gentle patience with which he listened to the beggars for knowledge, and the simple way in which he conveyed to their imperfect intelligences the truths they were seeking. Their self conceit was often offensive; but he knew it was the product of ignorance, and his effort was to cure the disorder. He was no more repelled by the disagreeable symptoms, than the physician is who must treat a loathsome disease. On one occasion, in my presence, one of these cripples refused to accept the instructions of the great physicist on a very simple question of dynamics, applicable to a project he had in hand; but instead of dismissing him, the master quietly took down "Hutton" from the bookcase, and patiently read that author's confirmation of the law he had been teaching. What an exhibition of true humility! Perhaps, thought he, "I can give a new direction to this man's mind, who may yet do something useful; and what matters it that he scorns me."

No one can form a just estimate of the vastness of his mind, of the extent and accuracy of his learning, and of his power to discern the correlations of knowledge, who has not carefully read the instructions mapped out by him for the guidance of investigators working under the auspices of the Smithsonian Institution. They constitute a set of charts, which, for years to come, will guide the explorer safely and surely in future voyages for the discovery of new truths; and are a monument attesting the fidelity with which the great trust was executed, and vindicating the sagacity of those eminent men, who, in 1846, saw, what his innate modesty forbade him to see, that Joseph Henry was, of all living men, the most fit to administer a fund whose object was "the increase and diffusion of knowledge among men."

Passing by thus hastily the great achievements illustrating the long and happy life of Henry, let us examine with more particularity his connection with the electro-magnetic telegraph; whose creation has so largely modified the course of modern civilization, and endowed the dull earth with nerves, like those of the living frame, whereby the whole body of mankind instantly feels the joys or sorrows of any of its members.

How to communicate intelligence instantly, over distances so great that the voice cannot be heard, had been well known to organized societies from remote antiquity. Visible signals, made by moving vanes by day, and lighted torches by night, were known to Greeks and Romans alike; and more recently the alphabet was associated with these movements, so that alphabetical messages were freely communicated.

Even barbarous nations and tribes possessed this art in a high degree of perfection; and the arrival and progress of Cortes in Mexico were communicated by telegraphic signals, corresponding with the sign language of the Aztecs, to the capital of the doomed Montezuma.

When atmospheric electricity came to be artificially generated, it occurred at once to ingenious men that it might be used for telegraphy; and, in 1774, the first electric telegraph ever constructed was established at Geneva by Lesage. He used 24 wires, each connected with an electroscope, whose function it is to move when the wire is charged with electricity, and by means of which any of the letters of the alphabet could be transmitted, by simply discharging a prime conductor of an electrical machine into the wire corresponding to that letter. This complicated apparatus was subsequently improved by using only one wire, and causing lettered wheels to revolve synchronously at the two stations, so that the same letter would appear at the same time to both operators. By this apparatus, whose principle of synchronous revolution is the same as that now used in the printing telegraph, the sender would simply close the circuit on his electrical machine when his revolving wheel presented the desired letter, and the pith-ball electroscope, moving at the receiving end at the same instant, would indicate to the receiver that the letter then presenting itself to him on his wheel was the one intended.

A number of other inventors used static electricity for the same purpose during the latter years of the last century, and the earlier ones of this. In England, Ronalds had a line of eight miles, on which the wire was suspended from poles, and insulated by silken strings; and in 1796, Salva, in Spain, worked a line by static electricity 26 miles long.

In the year 1800 Volta produced the voltaic pile, and gave to the world that new manifestation of electricity called "galvanism." In that form this subtle agent is far more manageable than in the form of static electricity; and by the use of galvanic batteries a current of low tension but of enormously greater power can be maintained with little difficulty; whereas static electricity is like lightning, and readily leaps and escapes from the surfaces on which it is confined. The galvanic current also readily decomposes acidulated water and many other substances, and this capacity was soon applied to the purposes of telegraphy. Sœmering, in 1807, invented a telegraph on this plan, and continued it for several years in Munich, publishing accounts of it in scientific journals, and exhibiting it to learned societies. Others followed in his lead, until finally it came into commercial use in England in 1846, as a rival to the electro-magnetic telegraph of later invention, but requiring its aid, as an alarm.

In 1820, Oersted discovered the capital fact that a galvanic current, passing through a wire placed horizontally above, and parallel to, an ordinary compass needle, will cause that needle to sway on its axis to the east or west, according to the direction of the current through the wire. At once Ampère suggested the application of the new discovery to the old telegraph, whereby galvanism might be substituted for static electricity, and the deflection of a magnetic needle for the divergence of the pith-ball of the electroscope. Baron Schilling, a Russian nobleman, inspired by the love of science, accordingly took up this suggestion and constructed a galvanometer or needle telegraph, which, in a practical and operative form, was exhibited to the Emperor Alexander in 1824, and came to be well known to scientific persons at that time.

In 1833, Gauss and Weber set up a *single circuit* galvanometer telegraph on this plan at Gottengen, leading the wire over the house-tops, on insulators, as we do now; and by the deflections of the needle to the right and left made up the alphabet, as it had been done before when using other means for moving the vanes.

Their apparatus, however, is perfectly silent. The needle is suspended by a thread when the noiseless current sways it to and fro with but feeble force; and it is incapable of calling the attention of the operator to receive its message. These were serious

Digitized by Google

difficulties, to be overcome by other principles and other inventions, which would supersede this one.

Following Oersted, Arago, in France, in 1820, made the next capital discovery. It was but a little thing he saw—simply that a sewing needle, surrounded by a coil of wire, through which a voltaic current passed, had become magnetic; but that little thing has grown to be mighty. This observation was the complete discovery of electro-magnetism, which had been dimly seen in Oersted's galvanometer, and was the germ of the electro-magnet. For *four years* this beautiful discovery was experimented with by all the scientists in Europe before another step was taken; and then William Sturgeon, of England, produced the electro-magnet. It consisted of a large soft iron wire, bent into a horse-shoe form, coated with varnish, and wrapped with a spiral coil of naked copper wire from end to end, through which the voltaic current might be passed. This bent wire became a magnet while the current flowed, but lost its magnetism when the current ceased.

Here, then, was born into the world an apparatus capable of exerting a strong power at the will of the operator, by merely opening and closing the voltaic circuit; and it was then thought that the difficulties in the way of the telegraph were conquered. The experiment was soon tried with Sturgeon's magnet by Barlow, an eminent scientist; and in January, 1825, he published his results in the *Edinburgh Philosophical Journal*, in these words:—

"The *details* of this contrivance "(a telegraph)" are *so obvious*, and the *principle on which it is founded so well understood*, that there was only one question which could render the result doubtful; and this was, is there any *diminution of effect by lengthening* the conducting wire?" If not, he proceeds to say: "Then no question could be entertained of the practicability and utility of the suggestion above adverted to. I was, therefore, induced to make the trial; but I found such a sensible *diminution with only two hundred feet of wire*, as at once to convince me of the *impracticability of the scheme*."

Barlow's experiment was repeated by other scientists in that and following years with a like result; until it came to be accepted in the scientific world that the telegraph could not be worked with the newly-discovered electro-magnetism. So strongly was this fixed in the opinion of the day, that as late as 1837—*thirteen years after the invention of the electro-magnet by Sturgeon*—so eminent a scientist and discoverer as Wheatstone pronounced the electro-magnetic telegraph impossible, on an occasion when the very question was submitted to him for decision by Cooke, at the suggestion of Faraday himself. This fact is so important, and so conclusive on the question now under examination, that I read Wheatstone's own account of it, submitted by himself to arbitrators who were to decide a controversy between himself and Cooke as to their respective merits as inventors of one form of the electro-magnetic telegraph. He says:

"I believe, but am not quite sure, that it was on the first of March, 1837, that Mr. Cooke introduced himself to me. He told me he had applied to Dr. Faraday, and Dr. Roget, for some information relative to a subject on which he was engaged, and they had referred him to me as having the means of answering his inquiries. * * Relying upon my former experience, I at once told Mr. Cooke that *it would not, and could not, act as a telegraph, because sufficient attractive power could not be imparted to an electro-magnet interposed in a long circuit;* and to convince him of the truth of this assertion I invited him to King's college to see the repetition of the experiments on which my conclusion was founded. He came, and after *seeing a variety of voltaic magnets which, even with powerful batteries, exhibited but slight adhesive attraction, he expressed his disappointment.*"

Cooke confirms this statement by saying: "It was my inability *to make the electro-magnet act at long distances* which first led me to Mr. Wheatstone."

Let the difficulty of making the discovery which overcame this impossibility be judged by the fact, that for so many years, such men as these were unable to do it when it was needed; and let that fact answer the envious suggestion that Henry's achievement involved no great amount of analytic and inventive power.

When Barlow's demonstration was published in 1824, Henry had never seen an electro-magnet, nor tried an experiment in electricity. When, however, two years later he took up the subject, and began the first set of regular scientific investigations ever attempted in the United States, he deduced from Ampère's law the principle that the voltaic currents, carried on wires around the iron core of the electro-magnet, should move in planes at right angles to the axis of that core—which they could not do even approximately if the core itself were insulated, as in Sturgeon's small magnet, having only one coil of naked wire wound spirally around it, necessarily leaving open spaces between the successive spirals, and so leading the current like a corkscrew around the core. He also reasoned that, as the current *must* be led through a spiral circuit, which theoretically should be circular, the departure from its true course might be counteracted by winding the wire on a second spiral outside of the first, but with its spiral angle opposed, so that the resultant of the current from the two spirals would be the same as if it revolved in planes at right angles to the axis of the core.

He brought his reasoning to the test of experiment. Instead of insulating the core, he wrapped a fine copper wire with silk, and wound it on the core; each spiral closely packed against its fellows, so as to correct the spiral error as much as possible in each layer; and then he wound the wire in a second spiral over the first, but with the pitch of the screw, so to speak, in the opposite direction. And carrying out the principle, he multiplied the coils to an enormous extent in the same way. The result justified and established his theory; and his magnets at once showed a capacity hundreds of times greater than any then known to science.

But this was not all. Another step had to be taken before Barlow's demonstration could be overthrown, and the telegraph made possible. And this he took by discovering and establishing the fact, that a magnet with a long fine wire coil must be worked by a battery of "intensity," composed of a large number of cells in series, when a *distant* effect was required; and that the greatest dynamic effect, close at hand, is produced by a battery of a very few cells of large surface, combined with a coil or coils of short coarse wire around the magnet.

These discoveries and inventions solved the problem which had seemed to European scientists insoluble; and in one account of them which was published in *Silliman's Journal* for January, 1831, he says: "The fact that the magnetic action of a current from a trough is at least not sensibly diminished by passing through a long wire, *is directly applicable to Mr. Barlow's project of forming an electro-magnetic telegraph.*" This reference was to Barlow's paper of 1824, in which he had demonstrated the impracticability of the telegraph.

Had these things been done in the Royal Institute, and read before the Royal Society, Wheatstone would not have been found, in 1837, denying the possibility of an electro-magnetic telegraph; and Faraday would have been able to answer Cooke's question, without sending him to Wheatstone for the information. In those days, however, the United States were held in no higher estimation in Europe than Nazareth was in former days in Jerusalem; and no one in England read an American book.

But not content with having reasoned out, and demonstrated, that *distance* was no longer the sole impediment in the way of the magnetic telegraph, Henry, in 1831, established the first electro-magnetic telegraph that ever existed. In the Albany academy he strung a mile of line wire, and with an "intensity battery" at one end, and his spool of long fine wire at the other, he operated the armature of the first *sounding* telegraph of any kind. When the armature was attracted by the magnet, it struck a small bell or sounder, which spoke its signals; and that apparatus there was maintained to illustrate the telegraph to the students.

When applied to practical use, some code of signals must be arranged for translating the successive taps of the armature; but that was well known in the telegraphic art for ages, needing only good judgment in arranging it, so that the letters which occur most frequently shall be represented by the smallest number of motions; just as Gauss and Weber arranged their needle telegraph code in 1833, when the movements of their needle to and fro, in a number of simple combinations, indicated the alphabet.

These "spools" of Henry have been the means by which most of the great discoveries in electro-magnetism have since been made. Faraday and Henry used them in their famous researches already referred to, in which they discovered magneto-electricity. Sturgeon, in writing of them, says: "Professor Henry has been enabled to produce a magnetic force which totally eclipses every other in the whole annals of magnetism; and no parallel is to be found since the miraculous suspension of the celebrated oriental impostor in his iron coffin." Without them we could not have the telegraph, or the still more marvelous telephone. They are to-day essentials of modern living, and are as familiar to us as spools of cotton. Judging by their results, they constitute the most important discovery which has ever been made in electricity since Volta created the battery.

Henry also put in operation at Princeton, in 1835, the very simple and obvious plan of using the "intensity spool and battery," working through long distances, to open and close the circuit of a "quantity spool and battery," stationed where the work was to be done; thus making the powerful magnet, at short range, the servant of the weak one at long range. In this state he left the problem entirely solved, to those who could procure the money to practically apply his discoveries to the commercial uses of man.

That task was no easy one. In 1831 there were no railroads and no steamships. Over rough country roads the mails were carried in wagons or coaches, and the postage on a single letter was a shilling for short distances, and twice as much for longer. But little capital had accumulated in this country; and corporations, those powerful instruments for uniting the slender means of the many into a compact force for the development of great industrial enterprises, were hardly known. If the most perfect telegraph apparatus of to-day had been then presented to the public, no company could have been formed to exploit it. The time had not yet come; nor could it come until railroads were built, and the exchange of material things had been rendered easy.

In Europe, where money and railroads were more abundant,

Digitized by Google

the telegraph was first put into practical use. Wheatstone and Cooke, in England in 1838—having first, however, seen and talked with Henry on the subject in 1837, *after* they had first decided the thing to be impossible—established a practical commercial telegraph line between Paddington and West Dayton, a distance of 13 miles; and a shorter line was in Munich. In this country private capital could not be raised for the purpose at all; not because there was any doubt that the thing could work, but because no one supposed it would repay the investment; as it certainly would not have done in those early days. At last Congress was induced to do what private enterprise refused, and in 1844, six years after the English lines had been in practical operation, and seven years after the Bavarian money was appropriated for the line between Baltimore and Washington. This was accomplished, after great exertions, by persons hoping for the reward which a patent for some of the contrivances connected with that particular plan promised.

Neither in England, where Wheatstone had a patent founded on Henry's inventions, nor here, where Morse had a similar one, could the telegraph have been introduced for years after it really was, but for the beneficent operation of the patent laws. But few men are to be found who will incur the risks, and expend the money, incident to the introduction of a new and untried industry, without the hope of that pecuniary return which, in such cases, can only be secured by the exclusive use for a limited time of the new thing, during which it is hoped that the original losses may be repaid, and a profit earned.

Let us now consider what would have been the position of Henry in the world, if at any time before his inventions had been put so long into practical public use that he had lost the rights to do so, he had taken a patent for—

First, His magnetic spools, pure and simple.

Secondly, The combination of a magnetic spool of long fine wire, with an "intensity battery," for the purpose of producing a practical magnetic effect at great distances.

Thirdly, The combination with such an apparatus of a quantity battery, operating upon a spool magnet of coarse and short wire, at a distance from the intensity battery; whereby the great lifting power of the quantity magnet might be controlled by the intensity combination.

And finally, The combination of the intensity battery and spool, with a vibrating armature, so arranged as to strike a sounder when the circuit is closed or opened at the sending end, for the purpose of transmitting intelligible messages telegraphically.

All these he might have patented in the United States at any time during several years after his discoveries and inventions were made; and he could have held them against the world. That he was the first man to do all these things is not in doubt anywhere. If he had taken such a patent, even as late as 1837, he would have controlled the telegraph in this country, certainly until 1851; and unless he had then been adequately rewarded for his great inventions, his term would have been extended till 1858. Imagine the good he would have done to science had the wealth which this would have produced been poured into his purse!

But listen to his noble words: "At the time of making my original experiments in electro-magnetism in Albany, I was urged by a friend to take out a patent, both for its application to machinery, and to the telegraph; but this I declined, on the ground that I did not then consider it compatible with the dignity of science to confine the benefits which might be derived from it to the exclusive use of any individual."

Pure science was his beloved, and he could not make merchandise of *her*.

When that sentence was written, other eminent scientists had thought differently of this question, and had patented their discoveries; and lest he might seem to cast a reproach upon them, and to say, "I am holier than thou," his humble spirit added these words: "In this, *perhaps*, I was too fastidious."

It must have occurred to him at times, when he needed money for his experiments, and when he saw the fruits of his labor enriching the world, that he *might* have taken some share of the wealth; but he would not taint with selfishness his generous gift. How valuable in money it was he knew full well. Even for that fragment of it, then for six years by him given to the public, which was carried to Morse in 1837 to enable him to construct his special plan of a recording telegraph in that year, now practically obsolete. Dr. Gale, who carried it, received a share in the patent which was founded upon it, and without which it could not have existed. For that share $15,000 in cash were subsequently paid to him. And its use for the telegraph was but a small part of its infinite variety of applications to the arts, and the purposes of man.

Come with me now into a telegraph office, and let us see what we find there. If the line be a short one, say 30 or 40 miles, you will see but one of Henry's spools, fixed to a table, having a piece of iron called an "armature," capable of vibrating in front of its poles, and so arranged that when the "spool magnet" attracts it, it will vibrate and strike a sounding-bar of sonorous metal, which gives out distinctly the sound of the tap. The "spool" is wound spirally in layers with several hundred feet of fine copper wire, covered with silk, in the manner specified by Henry in *Silliman's Journal*. At the other end of the line is a battery, composed of a number of cells in series, called by Henry for distinction an "intensity battery"; and the wire circuit is supplied with a simple device, so that it may be opened or closed by the operator's finger. When he closes it, a current of electricity flows from the "intensity battery" along the wire, and around the coil of the "intensity magnet," and the armature strikes the sounder and gives the signal. The listener hears it; and as the order of the taps progresses in accordance with a pre-arranged artificial code, to express the letters of the alphabet by combinations of successive taps—just as the old visible signals were arranged by combinations of the successive movements of the vanes, or afterwards of the needle of the Gauss and Weber telegraph—he hears letter after letter tapped out, and the message is understood.

Now, that apparatus has nothing about it more than was in Henry's Albany telegraph of 1831; nor could it operate if it omitted any one of the inventions, either singly or together, which were then for the first time combined. It depends entirely upon the discoveries made by Henry before 1831; and it could not have existed in the world earlier than those discoveries, by the use of any means then known to man; nor since by any other means than those discovered by Henry.

Henry used a bell as a sounder; they now use a metal bar and a sounding box. Henry reversed the battery current, whereby no spring is needed to withdraw the armature for the purpose of vibrating it; and that is the common practice in English and German telegraphs. Here they generally merely interrupt the circuit, and the armature is withdrawn from the magnet by a spring; although Henry's device is also used here largely, and is essential to the quadruplex instruments.

If, however, the telegraph line is a long one—it may be a thousand miles or more—then you will see two sets of Henry's spools, and two batteries. One is the "intensity battery and spool" first described; and the coil of fine wire may be, and often is, several thousand feet long—while the battery is composed of more than a hundred cells. The distance being so great, they do not attempt to send force enough through the intensity circuit to operate a sounder, but only to open and close the local circuit of Henry's quantity battery and spool. That circuit consists of a battery of but one or two cells of large surface, and a spool with about a hundred feet of coarse wire wound around its core. The intensity combination opens and closes this quantity circuit, whose armature strikes the sounder, just as the intensity armature itself does on shorter lines. This obvious plan Henry described and exhibited in Princeton to his classes, long before any magnetic telegraph was ever commercially constructed, or the convenience of such an arrangement had resulted from the great length to which the lines are stretched.

Upon that apparatus there are but four names to be written —Oersted, who discovered the effect of the voltaic current upon the magnetic needle; Arago, who discovered that the voltaic current could generate magnetism; Sturgeon, who produced the first electro-magnet; and Henry, who discovered the conditions under which an electro-magnet might be operated at a distance—who invented the devices by which it could so operate—and who applied those devices to an operative telegraph, of the same form and substance as that now in use all over the world. Beyond their discoveries and inventions nothing is essential to the present telegraph, except that which was of common knowledge when those discoveries were completed, and that ordinary mechanical skill which is far below the level either of discovery or invention.

This is the record, and so it will stand forever.

"The moving finger writes; and having writ,
Moves on: nor all your piety nor wit
Shall lure it back to cancel half a line,
Nor all your tears wash out one word of it."

Forty years had fled away since as teacher and pupil we first met, and they seemed like a dream that is past, when again we met to part forever in this world. In the chamber where the angel of death hovered over him, just ready to call him away, he talked thankfully of the past, and hopefully of that eternity on whose verge he stood. The vigor of youth and of manhood had been all spent in the service of humanity, and his strength was gone. The pallor of disease had dispelled the delicate hues of health, and time had traced its furrows on his brow. But the unclouded intellect still held its sway, enthroned in that magnificent head on which the snows of many winters had drifted; and the gentle loving spirit still, as of old, illumined his beautiful face, but with a clearer, warmer light, reflecting the heaven upon which he gazed. For himself he had but one regret—that he had not been spared to complete his last great labor, by which he hoped to confer still one more benefit upon humanity, by discovering some means affording greater security for mariners on the treacherous coast, when fogs shut down their impenetrable veils over the lights, and the syren's voice fails to pierce the fickle air.

The faithful servant—faithful unto death—only mourned that he could not have done more. With the humble spirit of the true Christian, after having, in the estimation of his fellow-men,

Digitized by Google

done so much, he, knowing better than others how much was yet to be done, exclaimed: "I am an unprofitable servant."

Such a life and such a death exalt and glorify humanity; illustrating and indelibly impressing upon our hearts the great truth, that man is made in the image of God.

"Along the smooth and slender wires, the sleepless heralds run,
Fast as the clear and living rays go streaming from the sun;
No peals or flashes, heard or seen, their wondrous flight betray,
And yet their words are quickly felt, in cities far away.

Nor summer's heat, nor winter's cold, can check their rapid course;
Unmoved they meet the fierce wind's blast, the rough wave's sweeping force.
In the long night of rain and wrath, as in the blaze of day,
They rush with news of weal or woe to thousands far away.

But faster still than tidings borne on that electric cord,
Rise the pure thoughts of him who loves the Christian's life and Lord;
Of him who taught, in smiles and tears, with fervent lips to pray,
Maintains high converse, here on earth, with bright worlds far away.

Aye, though no outward wish is breathed, nor outward answer given,
The sighing of that humble heart is known and felt in heaven.
Those long frail wires may bend or break, those viewless heralds stay;
But faith's last word shall reach the throne of God, though far away."

THE INSULATED OFFICE-WIRE CASE.

THE WESTERN ELECTRIC MANUFACTURING COMPANY *v.* THE ANSONIA BRASS AND COPPER COMPANY.

Supreme Court of the United States.

APPEAL from the Circuit Court of the United States for the District of Connecticut.

Decided April 20, 1885.

Complainant's reissued patent for an improvement in insulating telegraph wires, which covers a product, falls with his original patent, which covered a process, for the following reasons:

1. The process consists in compressing the wax or other suitable material into the pores of the fibrous covering of the wire without scraping off any part of it. This process was anticipated by letters patent to Dundonald and to Baudouin in Great Britain, which describe the compressing of the wax, &c., to attain the same result, namely—the insulation of the wire. The patent is therefore invalid.
2. The difference between the complainant's and the Baudouin process consists merely in the use of a greater quantity of wax. This may be an improvement on the latter process, but it does not involve invention.
3. The allegation of complainant's that one of the features of its process is allowing the wax to cool before compressing it is not sustained by any mention of this feature in either the specification or claim of its patent. As the claim fails to describe this feature, it cannot be held to be covered by the patent.

STATEMENT.

The case was a suit in equity brought by the appellant, the Western Electric Manufacturing Co., against the Ansonia Brass and Copper Co. to restrain the infringement of two reissued Letters Patent, numbered 6,954 and 6,955, respectively, granted to the appellant as the assignee of Joseph Olmsted, both dated February 29, 1876, for improvements in insulating telegraph wires. The reissues are divisions of original Letters Patent No. 129,858, dated July 23, 1872. The descriptive specifications of the two patents were identical. They differed only in the claims, the first being for a process and the second for the product of the process. The specification of both patents, after stating that Olmsted had invented a new and useful improvement in insulating telegraph wires proceeded as follows:

The method of insulating now in use consists in braiding over the wire a fibrous covering, after which it is dipped in wax for the purpose of filling and closing its pores, and, after a subsequent scraping to remove the surplus wax, it is ready for use. This method is, however, objectionable, inasmuch as it leaves the covering in a very rough and soft condition, and fails to secure perfect insulation.

In my improved method, after the wire has received its coating I dip it in paraffine or wax, after which, instead of scraping off the surplus coating, I pass the whole through a suitable machine, which compresses the covering, and forces the paraffine or wax into the pores, and secures perfect insulation. By so compressing the covering the paraffine or wax is forced into the pores, and the surface becomes and appears polished.

Wire insulated in this manner is entirely impervious to the atmosphere, of greater durability, and less cumbersome than any heretofore made

The claim of the process patent (No. 6,954) was as follows:

The method of insulating telegraph wires, by first filling the pores of the covering, and subsequently compressing this covering, and thereby polishing its surface, substantially as described.

The claim of the product patent (No. 6,955) was—

An insulated telegraph wire the covering of which has its pores filled and its surface polished, substantially as described.

The defendant denied in its answer that Olmsted was the first and original inventor of the improvement described in the patents, or of any substantial or material part thereof, or that the same was patentable or the subject-matter of invention, and that the alleged invention had been previously patented by Letters Patent of Great Britain, granted to Thomas, Earl of Dundonald, dated July 22, 1851, and by Letters Patent of Great Britain granted to Felix M. Baudouin, dated April 3, 1857. The defendant also denied infringement. The Circuit Court, on final hearing, dismissed the bill, and the plaintiff appealed.

Mr. George P. Barton for the appellant.

Mr. William B. Wooster for the appellee.

Mr. Justice Woods delivered the opinion of the Court.

It is clear that the two patents must stand or fall together. If the patent for the process is invalid, so must be the patent for the product. What we have to say will refer to the process patent. The alleged invention described in the patent is not for insulating telegraph wires, for that art long antedated the original patent. The specification disclaims as a part of the invention the braiding of a fibrous covering over the wire and then dipping it in wax for the purpose of filling and closing the pores, and the subsequent scraping of the surplus wax from the wire The patent does not cover the material in which the wire, after it has received its fibrous coating, is dipped, which may be either paraffine, wax, or bitumen, or any other suitable material. The three substances mentioned had long been used for that purpose. Nor does the patent specify or cover any device by which the process is to be carried on. Any suitable machine may be used. The process described by the patent consists, therefore, simply in this: After the wire has received its fibrous coating and been dipped in paraffine, wax, or other suitable substance, the compressing and forcing of the paraffine, wax, or other substance without scraping off any part of it, into the pores of the fibrous material by some suitable means. We think this process was not new. It was substantially anticipated both by the process described in the patent of Dundonald and in that of Baudouin, the first dated January 22, 1852, and the other April 3, 1857. Dundonald describes his process thus:

I also employ a bituminous material to cover, and thus insulate, the conducting-wires of electric telegraphs which are intended to be placed underground. For this purpose I employ the said bitumen, either simple or compounded, of a flexible description, and pass the wire through it when it is in a melted state, then causing the wire to pass through some die or orifice which will deprive it of all the superfluous bitumen. * * The incasement of this wire with bitumen may also be effected by covering it with a filamentous material which has been previously saturated with melted bitumen, and then passing the wire so covered through a heated die or orifice, so as to melt or soften the bitumen upon the filamentous material, and press the whole of the coating against the wire in such a way as to cause it to form one compact continuous covering of the wire, and thus insure its insulation.

The patent of Baudouin describes his process as follows:

My invention relates to the preparation of conductors of electricity for electric telegraphs, being wires insulated to prevent the loss or deterioration of the electric currents used for that purpose, and also in the machinery for the preparation or manufacture of such conductors. I coat the wires with bituminous or such like fatty matters that are not liable to become hard or cracked, but, on the contrary, are constantly acted on by the temperature of the atmosphere. Coatings of this material in themselves are insufficient to maintain the proper protection and insulation for telegraph conductors, but when combined with other materials—such as paper, woven fabrics of cotton, silk, wool, or hemp, in a particular manner—are well adapted for the purpose.

I prefer to use three ribbons and bobbins for this purpose, the first covering of the wire being enveloped by the second in such manner that the helical junction of the first ribbon is covered by the second, and the second by the third. The wire is passed through a bath of hot bitumen, and has the superfluous matter removed by passing through suitable dies or parts to scrape and smooth its surface and render it of uniform thickness. The first and second ribbons are also passed through bituminous or other suitable matter to render them more impervious to electricity. The coated and lapped wire is passed through suitable dies to remove superfluous matter, to smooth down the lapping of the ribbons, and to compress and cause their proper adhesion. The coated and lapped wire passes through dies or smoothing-holes both in entering and leaving the rotating frame. These dies or smoothers have a rotary motion, the better to enable them to wipe and smooth the coated wire.

It is plain that these patents anticipate the process set out in the specification of the Olmsted process patent. They all three describe the compressing of the wax, paraffine, or bitumen coating of a wire covered with the fibrous material, so as to attain the same result—namely, the insulation of the wire. The Olmsted patent, therefore, covers an old process applied to the same subject with no change in the manner of applying it, and with no result substantially distinct in its nature. It cannot therefore be a valid patent. *Penn. Railroad* v. *Locomotive Truck Co.* U. S., 490; *Vinton* v. *Hamilton*, 104 U. S., 485.

The fact that in the process described in the Olmsted patent the surplus wax or paraffine is not scraped off, but all that adheres to the wire is compressed against it and forms part of the covering, is relied on to distinguish that process from those of Dundonald and Baudouin; but the Dundonald process does not differ in this respect from that of Olmsted, for in the Dundonald process the whole of the coating is pressed against the wire and is left to form the covering; and as to the Baudouin process, the difference consists merely in the use of a greater quantity of wax or paraffine to form the coating. This may be an improvement upon the Baudouin process, but it does not involve invention.

So far as the present case is concerned, another answer to this contention of the appellant is that in this respect the defendant follows the Baudouin, and not the Olmsted process, by scraping off the superfluous coating material.

It was insisted in argument by appellant's counsel that one of the features of the process described in the Olmsted patent was the allowing of the wax or paraffine covering to cool before compressing it upon the wire, and as this was not done in the Dundonald or Baudouin process they did not anticipate the Olmsted process. But neither the specification nor claim of the Olmsted patent mentions as a part of the process the cooling of the wax or paraffine coating before compressing it upon the wire. The appellant's counsel, however, contends that it must be considered a part of the process, because the polished appearance of the surface of the covering described in the specification is the result of allowing the paraffine or wax to cool before compressing it upon the wire. But, clearly, a patentee cannot claim the benefit of an element of his invention thus vaguely and indefinitely hinted at. The law in force when the patent of Olm-

Digitized by Google

sted was issued (Act of July 8, 1870, section 4888, Revised Statutes) requires that—

Before any inventor shall receive a patent for his invention or discovery he shall file in the Patent Office a written description of the same and of the manner and process of making, constructing, compounding, and using it in such full, clear, concise, and exact terms as to enable any person skilled in the art or science to which it appertains or with which it is most nearly connected to make, construct, compound, or use the same, and he shall particularly point out and distinctly claim the part, improvement, or combination which he claims as his invention or discovery.

It is clear that if the patentee intended to include the cooling of the wax or paraffine before compressing it upon the wire he has failed to describe in his specification that element of his invention, as required by the statute. Instead of describing the process he mentions a quality of the product and asks the Court to infer the process from that quality. Such a vague and inverted method of description is not a compliance with the statute. That part of the alleged invention is not even referred to in the most distant manner in the claim. It has been held by this Court that—

The scope of letters patent should be limited to the invention covered by the claim; and though the claim may be illustrated it cannot be enlarged by the language in other parts of the specification. (*Railroad Co.* v. *Mellen*, 104 U. S., 112.)

The element of the process under consideration cannot, therefore, be held to be covered by the patent. The contention that the patentee intended to include it in his process is evidently an afterthought.

The result of the views expressed is that both the patents sued on are void.

Decree affirmed.

THE BRUSH-SWAN ELECTRIC LIGHT CO.

The offices of this company have been removed to numbers 204–210 Elizabeth street, New York city. There will be on exhibition at these rooms, all of the varieties of electric lighting apparatus manufactured under the Brush-Swan patents.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

President J. F. Morrison, announces that all electric light companies, manufacturers of electric light apparatus, machinery and supplies, who desire to become members of the National Electric Light Association, must make application on or before August 1st, 1885. All communications addressed to him at Baltimore, Md., will receive prompt attention. The next meeting of the association will be held at the Union Square Hotel in this city on August 18th.

THE NATIONAL TELEGRAM COMPANY.

Although the general news of the day is collected, and distributed by different press associations, they do not cover the entire field for the reason that many newspapers require a special service embracing various matters, in which their readers are particularly interested. It is for the purpose of performing such supplementary service that the National Telegram Co. has been organized by C. H. Bogle and W. C. Pearse, both of which gentlemen have been for many years identified with the press and telegraphic service. Base-ball and other sporting intelligence will be judiciously served out, and the sermons of popular divines transmitted to such journals as desire them Special sales of goods will also be carefully reported. The company will patronize all the different telegraph lines.

THE ELECTRICAL EXHIBITION TESTS.

Although the actual tests at Philadelphia have been substantially completed, the task of calculating and classifying the results from the great mass of recorded data will require some weeks of hard labor, which the continuance of the present insufferable hot spell may serve to prolong. The announcement of certain results alleged to have been obtained, which has been made in several of the daily newspapers, and which has called forth some adverse criticism, is entirely premature.

THE TRAIN-DESPATCHERS' CONVENTION.

The American Train Despatchers' Convention, held recently at Denver, adopted a uniform system of rules and train orders. They favor the use of double orders when practicable; recommend that conductors be only required to sign train orders; favor trains losing their rights after becoming 12 hours late; recommend the use of time orders; favor in cases of emergency the running of trains against "hold orders" signed by the agent or operator; recommend that all conductors be required to pass an examination on time card and rules regarding running of trains, and recommend the use, both day and night, of stationary train-order signals, red and white—the normal position to be white, and moved to red when it is desired to hold trains.

SUIT BROUGHT ON THE SAWYER-MAN PATENTS.

On June 22d the Consolidated Electric Light Co. filed an application in the United States Circuit Court against Thomas A. Edison and the Edison Electric Light Co. for an injunction restraining the defendant from making, using, or selling the conductors for incandescent lights made of carbonized, fibrous, or textile material.

The injunction asked for is the result of a long period of fighting between Mr. Edison and William E. Sawyer as to the priority of discovery of carbon conductors of fibrous material. In January, 1880, the war began in the Patent Office as to whom the patent for such fibrous carbons was due. Commissioner Marble decided that Sawyer was entitled to the patent. Then came a time of appeals and applications for rehearings on Mr. Edison's part, but on May 12th last the patent was granted to Mr. Sawyer, or rather to the Consolidated Electric Light Co., which profited by his discoveries, as Sawyer died during the proceedings. H. R. Garden, who is one of the counsel for the Consolidated Electric Light Co, says that it will not be the company's policy to fight consumers in the suit against the Edison company. It simply does not wish the Edison people to go on manufacturing the carbon filaments without recompensing the company owning the patent. The motion for a preliminary injunction will be argued before Judge Wallace in the United States Circuit Court in a few days.

WESTERN UNION QUARTERLY STATEMENT.

The directors of the Western Union Telegraph Co. have declared a dividend of 1¼ per cent. for the quarter ending June 30. The statement on which the dividend was declared assumes that "the net revenues of the quarter ending June 30, inst., based upon nearly completed returns for April, partial returns for May, and estimating the business for June, will be about $1,400,000." If the company should really earn the amount estimated there would be a balance of $56,391 on the operations of the quarter. This would swell the "surplus" of the company to $4,303,334. Compared with the quarter ended June 30, 1884, the items stand:—

Net revenue (estimated)	$1,400,000	Dec	$350,000
Interest and sinking fund	143,768	Dec	232
Balance	$1,256,232	Dec	$349,768
Dividend 1¼ per cent	1,199,841	Dec	199,959
Balance	$56.391	Dec	$149,809
Surplus April 1	$4,246,943	Inc	197,126
Total surplus July 1	$4,303,334	Inc	$47,817

The dividend of one year ago was 1¾ per cent.

ELECTRIC LIGHT AND POWER.

The Salem (Mass.) Electric Light Co. has declared a semi-annual dividend of 3 per cent.

The Middlesex Electric Light Co. of Lowell, Mass., has re-elected its directors. The annual report shows: Gross receipts for the year $43,407.66; expenditures, $43,241.08; balance May 31, 1885, $166.58. The receipts from lights were $38,406.94; lighting expenses, $22,239; construction expenses, $9,340.93; lights in use, 235. The net earnings for the year were $11,497.90, or 8.7 per cent. on the 13,106 issued shares. The net receipts were applied to improvements, interest, etc., so that no dividend was declared. The balance sheet shows temporary loans of $20,000.

There are now 278 public and private arc lamps used in Hartford, Conn., and 16 more have been ordered which is beyond the supply of the present plant. A 75 h. p. engine and two 45-light dynamos are to be added.

The Cleveland Electric Light Co. has put in two additional dynamos and a third Westinghouse Automatic Engine.

The Lewiston (Maine) Electric Light Co., now uses saw-dust for fuel, costing only 75 cents per cord delivered. It finds this fuel more economical than screenings for making steam. Its boilers are set with the Jarvis patent setting, and use Sheffield grate bars. It uses the Armington & Sims engines belted direct to the dynamos.

A 200-light Weston incandescent plant has been installed in the College of Ottawa, Ottawa, Ont., by Ahearn and Soper of that city, representing the U. S. Electric Lighting Co.

The Jamestown (N. Y.) Gas Co., is preparing to introduce incandescent lighting into the business portion of the city. The system to be adopted is now under advisement.

The city of San Diego in southern California will soon be lighted by electricity. An effort is being made to organize a similar movement in Santa Barbara.

The Woolley Electric Light Co. is fitting up an entire train on the C. I., St. L. & C., to light it by electricity, the same engine that runs the machinery for the locomotive's electric headlight to furnish the power which lights the train.

Digitized by Google

The Badger Illuminating Co. has been incorporated in Illinois to furnish electric lights and manufacture electric apparatus; capital stock, $64,000; incorporators, Leonard M. Hodges, Henry P. Robbins, Alpheus C. Badger.

The Newark, N. J. city council has accepted the proposition of the United States Electric Lighting Co. to light the city. The same company expects to soon erect a tower light in Orange, N. J.

On May 26th the new station of the Municipal Electric Light Co. of Brooklyn, E. D., was opened. It is a new and substantial brick building 60x100 feet. The present plant consists of five Buckeye engines with a total of 390 h. p. driving 10 dynamos. The lighting capacity is about 400 arc lamps. There is sufficient space to permit the increase of machinery to double the present amount.

The New London Electric Light Co. is putting in a 60 h. p. Westinghouse engine.

The Superior and Duluth Electric Light Co. has filed articles of association with the Secretary of State in Illinois, its object being to furnish electric light and power in the county of Douglas, Wisconsin, and the county of St. Louis, Minnesota. The capital stock is $100,000, divided into 1,000 shares, and the incorporators are J. H. Hammond, C. H. Catlin and W. V. Noad.

An effort is being made to establish an electric light plant at Greenfield, Mass., and a committee has been appointed to make arrangements to see where the most central point will be for its location. Quite a number of the citizens have expressed a willingness to light their places of business by it.

MANUFACTURING AND TRADE NOTES.

The carbons made by the Forest City Carbon M'f'g Co., Cleveland, Ohio, for whom Messrs. Holmes, Booth & Haydens are sole agents, are giving excellent satisfaction, and although they have been on the market but a very short time, their sales are increasing so rapidly that they are now building a factory 50x200 feet in which they will put the best machinery, and will soon be able to turn out about 600,000 carbons per month.

SUBTERRANEAN LINES.

Mayor Low of Brooklyn, has appointed G. W. Plympton, Rossiter W. Raymond and John Reynolds, as Commissioners to enforce the law for placing the wires underground.

SUBMARINE CABLES.

A despatch from Buenos Ayres says that Minister Osborn, acting in accordance with instructions received from the State Department, Washington, has concluded a contract securing to the Central and South American Telegraph Co. a concession to establish cables between Buenos Ayres and Rio Janeiro and land lines between Buenos Ayres and the Pacific side, thus securing to an American company continuous and independent telegraphic communication between the United States and Brazil. The necessary decree has been signed by the President of the Argentine Republic.

THE TELEGRAPH.

At Chicago on June 6, Judge Blodgett granted the Postal Telegraph Co. an injunction restraining E. A. Howell, of Pennsylvania, from obtaining execution of a judgment of $61,266, the company representing that to sell any portion of its lines would seriously damage its entire property.

The Bankers and Merchants' company has announced the following rates at Boston. 10 cents to New York, Providence, Hartford, Fall River and Newport; 20 cents to Philadelphia, Baltimore and Washington; 25 cents to Chicago, Cleveland, Buffalo, Rochester and Pittsburg.

The Baltimore and Ohio Telegraph Co. is preparing to mount its long-distance messengers on bicycles at Saratoga, Long Branch and Niagara Falls. If the pace is too slow the machines will fall over, and it is believed that little difficulty will be experienced in recruiting the force.

At the annual meeting of the Association of Railroad Telegraph Superintendents, held at Cleveland June 17, the following officers were elected: C. W. Harmon, St. Louis, president; George L. Lang, Boston, vice-president; P. W. Drew, Chicago, secretary and treasurer. Explanations were given of two systems designed to utilize inductive effects of currents of electricity, whereby messages can be sent to and received from moving trains. The association will next meet in St. Paul, June 18, 1886.

THE TELEPHONE.

The total number of telephone exchanges in existence in this country Jan. 1st, 1885, was 772. Miles of wire in use, 101,734. Employés, 5,168. Subscribers 134,847. The increase in the number of subscribers during the year 1884 was 11,222.

An answer to the patent infringement suit of the Bell Telephone Co. against the Western Pennsylvania Telephone Co. was filed in the United States Circuit Court at Pittsburg, Pa., June 23. The defendants deny the validity of the Bell patent on the ground that the invention was known 15 years before Bell or Edison took out patents by which control of the system is now claimed.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER *by* Pope & Edgecomb, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From May 12th, to June 9th, 1885 (inclusive).

Alarms and Signals:—*Bells*, C. Henzel, 318,472, May 26; A. H. Palmer, 318,647, 318,674; E. F. Recordon, 319,318, June 2. *Burglar Alarm*, J. Barkheimer, 319,058. *Automatic Responding Instrument*, A. G. Holcombe, 319,-718, June 9. *Programme Signal*, R. B. Carr, 319,782.

Clocks:—*Alarm Clock*, Victor Gallet, 318,612, May 26. *Secondary*, C. A. Hussey, 319,259, June 2. *Circuit closer for Clock*, W. F. Weisberger, 319,534, June 9. *Watchman's Clock*, R. B. Carr, 319,783. *Watchman's Time Recorder*, A. Howard, 319,818.

Commutators:—*Connecting Device for Switch-boards*, E. W. Smith, 318,929, May 26. *Switch*, A. J. Holt, 318,987, June 2. *Automatic Cut-off for Batteries*, L. Soulliere, 319,635, June 9.

Conductors, Insulators, Supports and Systems:—*System of Electric Light Distribution*, J. C. Allen and S. A. W. Gould, 317.960, May 19; W. S. Andrews and T. Spencer, 318,157; W. M. Thomas, 319,347, June 2. *Manufacture of Insulating Material*, J. L. Clark, 318,233, May 19. *Electric Way*, W. E. Banta, 318,411. *Joint for Pipes*, Wm. Hassall, 318.616, May 26. *Composition for Preserving Insulating Tubing*, J. W. Ellis, 319.079. June 2. *Preparation of Insulating Material*, J. A. Fleming, 319,084. *Underground Conductor*, B. L. Nevius, 319,112. *Machine for Making Insulator Clips*, E. Dodge, 319,206. *Conductor*, W. H. Sawyer, 319.326, June 2. *Conduit for Conductors*, W. Cohlman, 319,197; B. L. Nevius, 319,420. *Supporting Bracket for Conduits*, G. B. Bryant, 318,951. *Insulator*, G. L. Broomhall, 319,447, June 9. *Method of Making Conductors*, J. J. Williamson, 319,536.

Dynamo Machines and Motors:—*Dynamos*, J. S. Dubois, 318,091, May 19; A. G. Waterhouse, 318,671, May 26; L. G. Woolley, 319,540, June 9; G. A. Hamilton, 319,578. *Armature for*, D. A. Schuyler, 318,664, May 26. *Motor*, L. G. Woolley, 318,589. *Engine*, W. A. J. Kohrn, 319,912, June 9.

Galvanic Battery:—*Carbon Battery Electrode*, H. F. B. Schaefer, 318,300, May 19. *Battery*, M. J. Myers, 319,923, June 9.

Ignition:—*Primer*, S. Russell, 319,627, June 9. *Cartridge*, 319,628, 319,629. *Fire-arm*, J. W. Frost, 319,898, June 9.

Lamps and Appurtenances:—*Arc*, W. F. Buckley, 318,350, May 19; L. G. Woolley, 319,539, June 9; H. Pieper, 319.745; A. Bossard, 319,781. *Combined Gas and Electric Lamp Fixture*, C. Deavs, 318,547, May 26. *Incandescent Lamps*, E. L. Roussy, 319,129, June 2; L. Heinze, 319,580, June 9. *Holder for*, A. Bernstein, 319,177, June 2. *Lighting Apparatus*, E. Arnould, 319,-380; H. B. Gale, 319,573, June 9. *Process of Carbonizing Paper*, S. E. Trott, 319,353, June 2.

Measurement:—*Meter*, J. Cauderay, 318,166, May 19.

Metallurgy:—*Process of Electro Depositing Copper*, Moses G. Farmer, 319,-687, June 9. *Process of Smelting Ores*, E. H. and A. H. Cowles, 319,795. *Smelting Furnace*, same, 319,945.

Miscellaneous:—*Apparatus for Registering the Flow of Fluid and Detecting Waste*, J. C. Ayer, 318,227, May 19. *Marine Governor*, B. J. Carroll, 318,417. *Automatic Instructor*, W. L. Gates, 319,224, June 2. *Governor for Steam and Fluid Engines*, A. L. Ide, 319.260. *Torpedo Boat*, W. S. Sims, 319,633, June 9. *Combined Electric and Water Ram*, F. E. Fisher, 319,805.

Protectors:—*Protection of Men from High Tension Currents*, P. B. Delany, 318,172, May 19. *Combined Lightning Arrester and Test Connection*, H. B. Lytle and J. A. McCoy, 318,571, May 26. *Lightning Arrester for Wire Fences*, 319,300, June 2. *Safety Catch Plug*, S. Bergmann, 319,384.

Railways and Appliances:—*Signaling Apparatus*, W. Hadden, 317,994, May 19. *Train Signaling*, E. T. Gilliland, 318,102. *Railway*, B. Bidwell, 318,594, May 26. *Method of Operating Electric Railway Trains*, F. J. Sprague, 318,668. *Railway Signal*, O. S. Hertzog, 318,186, May 19; S. C. Pullman, 319,023, June 2. *Rail for Electric Railways*, S. F. Van Choate, 319,041.

Storage Batteries:—J. W. Swan, 318,828, May 26.

Telegraphs:—B. K. Boyle, 318,315, May 19. *Key and Sounder*, P. P. Belt, 318,854, May 26. *Sounder*, J. W. Delmege, 319,201, June 2. *Quadruplex*, G. Smith, 319,428. *Printing Telegraph*, G. B. Scott, 319,885, June 9. *Paper-Guard for*, C. Winkel, 319,770. *Unison Device for*, L. A. McCarthy, 319,001, June 2.

Telephones and Apparatus:—*Mechanical Telephone*, J. C. Rounds, 318,397, May 19. *Telephone Attachment*, G. R. Tyler, 318,057. *Transmitter*, E. H. Johnson, 319,415, June 2; J. P. Freeman, 318,423, 318,424, May 19; A. Berthon, 319,548, June 9; S. P. Nutt, 319,927. *Exchange*, J. A. Seely, 318,514, May 26; F. Shaw and W. A. Childs, 319,856, June 9. *Telephone Apparatus*, H. E. Waite, 319,043, June 2. *Telephone*, J. D. Husbands, 318,907, May 26; H. E. Waite, 319,042, June 2; C. E. Allen, 319,048. *Switch*, H. W. Comstock, 319,-789, June 9.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

NEW YORK, AUGUST, 1885.

THE NATION MOURNS.

UPON Mount McGregor's summit, repose the mortal remains of America's greatest general, Ulysses S. Grant. Through his many months of patient suffering, the whole civilized world has watched the gradual encroachment of the final conqueror, to whom all must eventually surrender.

With the flitting of his last breath on the morning of July 23d, the telegraph, which in the past had been a most efficient aid in his achievement of victory, distributed the sad tidings of his death to the uttermost parts of the earth. Enshrined in the heart of the humblest citizen, whatever may be his nationality; loved and respected alike by democracy and royalty in every land, his fame will endure throughout all future ages.

Reflecting upon the grave circumstances through which he was enabled to attain distinction, let us hope that the humanizing influence of closer intercourse between nations, through the medium of electric communication over land and under sea, may eventually substitute the more enlightened measures of diplomacy for the barbarous acts of war.

SOWING THE WIND.

THE final disposition of the effects of impecunious and insolvent telegraph companies has usually heretofore been a very peaceful operation and one quietly acquiesced in by all interested parties, who recognized the hopelessness of a never-ending struggle against adversity. That the growth of competitive telegraph systems has for the most part gone on in the face of a series of hardships, arising from lack of capital, and in many cases of good management, to say nothing of the machinations of a wily opponent, all will admit who have ever participated in their exploitation, even in the most humble capacity. To the responsible managers of such concerns, consolidation is not infrequently welcome as a relief from the importunities of creditors and the supplications of unpaid employés. The recent seizure by the Western Union Telegraph Co. of the greater portion of the wires composing the system of the Bankers and Merchants' Telegraph Co., which was executed simultaneously and synchronously in various parts of the country, was perhaps the most sensational development in the way of telegraphic litigation that has yet been witnessed. The interests of the various bondholders, lessees, receivers, creditors and agents formed an almost unprecedented legal complication, which afforded an opportunity for the Western Union management, under color of lawful authority, to cut down and take possession of its competitor's working telegraph wires, without the slightest pretense of giving the formal notice required by common law, to say nothing of common decency. Except that human life may not have been endangered, this was an operation comparable to the sudden removal of a railway drawbridge over which trains were continually passing. We like to call ourselves a law-abiding people, and we sometimes are inclined to boast, especially in times of riot and excitement, that under a republican form of government almost every citizen can be depended upon to submit to the edicts of the civil authorities. But there are certain corporations which, under the protection of our national, state and municipal governments, have been permitted to clothe their executive officers with almost dictatorial power. Armies of employés are compelled to execute the decrees of these officials, or suffer the penalty. The consequence of refusal is not merely immediate loss of employment, for instances are not wanting where such corporations have even pursued the victim beyond their own jurisdiction, seeking to prevent him from honestly earning his bread under other masters. We refer to these facts as an example of the pressure of discipline under which honest-minded men may be forced to perpetrate acts they well know to be illegal, trusting to the implied protection of their wealthy and powerful employers for immunity from punishment. Having been granted a giant's power, these corporations elect to use it like a giant. It is very certain, however, that the people are becoming jealous of the creature of their own devising. Corporate strength has hitherto been respected because it has seemingly entrenched itself behind the law, unjust though it may appear to be. Now, however, under the feeble subterfuge of a "receiver's agency," the employés of the Western Union Telegraph Co. enter upon the premises of a neighbor and seize such property as they choose, regardless of the fact that this company has no jurisdiction over the whole, even if it has over a part, while the parties wronged are coolly informed that they may resort to the courts. So, too, may the man who is knocked down and robbed in the highway, but it can scarcely be pretended that the act of violence is thereby rendered legal. As a matter of policy, nothing can possibly be more injudicious than for a corporation like the Western Union, whose unguarded property is scattered over half a continent, to establish the hazardous precedent

Digitized by Google

of using force and violence to accomplish its ends. The private citizen, or a mob of private citizens, may at some future time take the law into their own hands, rather than await the results of the slow operation of legal machinery. The people have submitted quietly to the gradual encroachment of these mighty engines of capital, but the keen-eyed observer sees many indications that a storm is brewing. That calm reliance upon the majesty of the law, and the physical support of the armed police and militia, will not always continue. How or when the storm will break, none are at present wise enough to predict.

In subsequently restoring property which should not have been meddled with, the Western Union company, although theoretically carrying out the instructions of the court, could not neutralize the designedly disastrous effect of the actual stoppage of business, and the consequent discredit which had been thrown upon its competitor's capacity for reliable telegraphic transmission. The very fact that the order of restitution was so readily complied with, is sufficient to prove that the seizure was unjustifiable; but the object aimed at—the crippling of a competing system—was effected, and the lapse of time will be depended upon to obliterate all permanent traces of the outrage.

DISTRICT MESSENGER SERVICE.

It will doubtless be a most surprising, not to say incredible piece of information to the New York public to be told that the supply of boys is actually running short. The gentleman who advertised a few days ago for an office boy at four dollars a week, apparently did not think so when upon his arrival at his place of business he found the entrance blockaded with applicants of all grades. It has been innocently supposed that the competition between the various district companies would naturally tend to bring about an improved service. This, however, does not by any means appear to be the case. Not only is the visible crop of suitable boys absorbed, but the constant demand for their services by rival companies relieves them from any serious apprehension as to the loss of employment in case of receiving what is technically known as the "bounce." It has long been observed that boys do not yearn for positions on the district messenger force. The struggle for existence, however, compels many parents to place their offspring in this service, for the simple reason that no more satisfactory opening presents itself. They are forced to submit to a more or less rigid discipline, as for obvious reasons, a congregated mass of New York boys can be controlled in no other way.

A thoroughly organized messenger service should be equal to any emergency, but the experience of the public in some of the New York districts proves that such is not the case, but that on the contrary there is much room for improvement.

Business men entirely dependent upon this source for messengers, naturally become impatient, when after repeated calls for perhaps an hour without response, they learn that because of the prevailing heat, the demand for messengers is unusually large, and that there are not boys enough to supply the demand. It might also be added that those actually in service cannot move so rapidly in hot weather, and the fact that by the arbitrary stupidity of the management they are obliged to be clothed in full winter uniform, with the thermometer at + 100° does not tend in the slightest degree to accelerate their footsteps. The prevailing low rates for telegrams by which their number has somewhat increased, together with the modern system of collecting messages by the district boys, compels the employment of a much larger force than was formerly the case. It is difficult to believe, however, that there is no remedy for this state of affairs. If messengers cannot be furnished promptly to collect telegrams, this branch of the service had better be dispensed with at once.

The business public never demanded this innovation; it is merely one of the outgrowths of fierce competition for public patronage. Having become accustomed to rely upon it, delays and failures which occur more or less frequently are a fruitful source of vexation and annoyance. Sufficient attention has already been paid to cheapening the telegraph service, but we would respectfully suggest that its improvement is still worthy of consideration, and would form a fine field of operations for some company. Every experienced telegraphic manager knows full well that the weakest point in the whole telegraph system is the messenger service. This is not a matter for scientific treatment, but it certainly is of sufficient importance to demand the application of practical common sense. But we may suggest that there are plenty of executive officers capable of managing men, who would fail ignominiously in coping with the ingenious insubordination of the small boy.

DOMESTIC ELECTRIC LIGHTING.

One of the most promising fields for electric lighting remains comparatively undeveloped. We have heretofore referred to the installation of isolated plants for incandescent lighting in factories, stores, hotels, and large apartment or office buildings. In most of these establishments steam plants are necessary for elevators, power, and heating, so that the additional care and expense of an electric lighting system may be provided for without proving a serious burden.

The lighting of country villas and suburban residences is, however, a problem more difficult of solution. Such an installation is extremely desirable in many cases, as the unquestionable perfection of the light from a sanitary point of view, would insure its adoption in numerous instances, at even double the cost of gas. A very important advantage is the exemption from the danger attending the use of friction matches. Where incandescent systems are operated from central stations, of course it is preferable to derive the light from that source, but there will always be a vast number of residences outside those districts which are now dependent upon illuminating oil from necessity rather than choice. A large proportion of these consumers would willingly adopt the incandescent light if it could be supplied at a reasonable price without annoyance. In England, Mr. Preece has adopted a storage battery system, supplied by a dynamo, the power being derived from a gas engine. Such an arrangement, however satisfactory to an expert, is rather too complicated for an ordinary householder. Storage batteries supplied by dynamos, and

Digitized by Google

operated by a company properly organized for such service, have been introduced in Cheyenne, and probably other cities. There the subscribers are merely called upon to pay their monthly bills, reserving, of course, the usual privilege of growling at their exorbitance. Right here it may be well to mention that a definite contract based upon a proper estimate of consumption, which experience should teach, would probably provide against those accusations of overcharging which have become chronic among many gas consumers. All private installations of gas, steam, water or electricity, are too apt to be neglected if dependent upon the casual supervision even of experts, who have more important matters to engross their attention. As a flagrant example of this, we have in mind a certain Morse telegraph line connecting the residences of several more or less distinguished electricians, which is not in working order for a continuous month during an entire year.

In providing for a system of domestic lighting such as we have suggested, the question of economy within reasonable limits is not the most important one. Its *general* introduction would of course depend in a great measure upon its cost, but there are very many people who in their homes will have the best, if at the same time it be the safest and the most healthful. A primary battery which will meet all the conditions, is at present the dream of many who are experimenting in this direction, and it is of course possible that some fortunate inventor may hit upon the particular combination leading to successful results.

TELEGRAPHIC ERRORS.

The question of responsibility for errors in telegrams is one which is continually presenting itself, and although telegraph companies universally require their patrons upon filing a telegram to sign a printed agreement to release the company from all liability for damage in consequence of mistake, delay, or non-delivery unless the message be insured, the courts have rendered various and by no means consistent decisions, in suits involving the question of responsibility which have been brought before them for adjudication. Almost every conceivable form of discipline has been devised in the vain hope of preventing operators from making these unfortunate blunders, while on the other hand, the much lauded improvements in duplex, quadruplex and automatic telegraph machinery which have been introduced within the past few years have tended to increase and multiply them. We doubt whether an artisan in any other vocation is so peculiarly situated in regard to the making of mistakes as the telegraphic operator, when he receives, as he necessarily must, by sound alone. In the first place he is often unjustly charged with errors which may have been wholly the fault of the transmitting operator, it being tacitly assumed that the sender follows his copy accurately and cannot therefore go astray. In the second place no opportunity can be afforded him to verify his work. If every operator was allowed to repeat each message back, or to take the necessary time to give it a careful examination after its receipt, the dividends earned by telegraph companies would be few and small, especially at the prevailing rates of service. The modern operator is driven by his distant colleague to copy messages legibly from the dictation of a sounder at an average speed of some thirty words per minute, far beyond that which is even deemed possible by penmen in any other branch of business. Each message as its end is reached is thrown aside for immediate delivery; the only safeguard of the operator is the mental counting of the words as his work proceeds, the number of which must compare with the numerical check. The comparatively few errors which are made by the expert operator, especially after the elimination of those fairly attributable to bad manuscript, of faults in circuits or apparatus, should be entitled to be regarded with leniency, even though it is impossible to overlook them entirely. It is, we think, doubtful, whether any system of discipline, legal punishment, or personal responsibility for damages, however stringently enforced, could be so efficacious as the simple feeling of professional pride, which if carefully cultivated, leads to the most salutary results. It is to be regretted that the gradual degradation of the service during the past few years, by the introduction of a large proportion of less intelligent, and therefore less highly paid employés—which is the more deplorable because utterly uncalled for and unnecessary—is slowly undermining that respect for their calling which is the soundest basis for excellence in the work of telegraphers, as well as all skilled operatives.

REIS vs. BELL.

The *Scientific American*, commenting upon the recent decision of Judge McKennan in the suit against the Western Telephone Co. at Pittsburg, to the effect that the prior decisions of Judges Gray and Wallace must be held to be an estoppel against the hearing of further argument in his court on behalf of the defense upon matters previously passed upon by those judges, although the defendants were prepared to introduce testimony to prove that their invention was substantially the same as that used by Philipp Reis many years prior to Bell's invention, says:

The practical effect of this decision is that the use of the Reis telephone is an infringement of the Bell patent—a position which we have expected the lower courts would sooner or later take, since in no other way can the gigantic Bell monopoly be upheld. The moment justice is done, and the use of Reis's invention be allowed, the patent of Bell will be reduced to its proper rank—that of a subordinate improvement. None of the Bell telephone litigations have reached decision by the Supreme Court. If the latter tribunal deals with the Bell patent in the same manner that it has with other wide reaching monopolies, the claims of the Bell people will, in due time, be greatly modified.

We have no authority to speak for the owners of the Bell telephone patents, but we hazard very little in saying that any person or corporation choosing to engage in the business of making, selling or using the Reis telephone, constructed as Reis constructed it, need not feel alarmed about their business being interfered with by the "gigantic Bell monopoly." The trouble appears to be that the courts are unable to see the justice of permitting the defendants in the case to construct telephones like Bell's. When somebody is enjoined from making and using a Reis telephone, unaided by patented improvements of later date belonging to others, it will be time enough for a scientific journal to assert that it is an infringement upon the Bell patent.

THE ELEMENTARY PRINCIPLES OF ELECTRICAL MEASUREMENT.

BY F. L. POPE.

(Continued from p. 261, Volume iii.)

PHENOMENA PRODUCED BY ELECTRICAL ACTION.

Having now obtained a somewhat definite idea of the characteristics of our units of measurement, we will next consider how they are to be used. We can only perform electrical measurements by observing certain *effects* of the electric current. These effects are exhibited in four different forms, viz., 1, *heat*, 2, *chemical decomposition*, 3, *electro-dynamic attraction*, and 4, *electro-static attraction*.

1. *Heat.*—When the positive and negative poles of an electric generator are united by a conductor presenting an inappreciable resistance, such as a thick wire or bar of copper, through which the current passes, the conductor is not perceptibly heated. If, however, we substitute for the thick conductor a thinner one, or one of poorly conducting material, which offers considerable resistance to the current, such a conductor will become heated during the passage of the current. If the sectional area of the conductor is sufficiently small in proportion to the quantity of electricity traversing the circuit, it may be raised even to a white heat, as we see for example, in the case of the luminous filament of the incandescent electric lamp.

Heat is developed by the oxidation of the zinc in the voltaic battery during the production of a current.

The total amount of heat generated by the oxidation of a given weight of pure zinc is always the same, and is, as we shall hereafter see, strictly proportional to the square of the strength of current, or quantity of electricity which traverses the circuit in a given time, but the heat thus generated may be distributed according to circumstances in different proportions between the battery and the external circuit. The facts as to the quantitative relations between electricity and heat were established by J. P. Joule, of Manchester, England, who carefully collected and measured the amount of heat developed in an electric circuit under known conditions. This method of electrical measurement is sometimes resorted to in practice, but other methods hereafter to be explained, are more convenient for most purposes and are therefore more commonly employed. The instrument known as the *galvano-thermometer* is based upon this property of the current.

2. *Chemical Decomposition.*—When an electric current traverses a compound liquid conductor instead of a metallic one, the conducting liquid undergoes decomposition. This fact was discovered by Nicholson and Carlisle in 1800. Faraday devised an apparatus called a *voltameter*, by means of which he experimentally proved that the quantity of liquid thus decomposed in a given time is strictly in proportion to the quantity of electricity traversing the circuit. The voltameter consists principally of a graduated tube, by means of which the bulk of gas generated in a given time is collected and measured. This instrument will be hereafter described. It is found very useful in certain classes of electrical measurements.

3. *Electro-Dynamic Attraction.*—When an electric current traverses a conductor situated in the vicinity of, and parallel to a freely suspended magnet (such for example as the needle of an ordinary compass), lying in the magnetic meridian, the magnet will be deflected from its normal position in the plane of the magnetic meridian, and will tend to assume a position at right angles to the plane of the conductor conveying the electric current. This fact was discovered by Oersted in 1820. The greater the strength or magnitude of the current, the more nearly will the needle approach a position perpendicular to the conductor. It is found that when proper precautions are observed, the angles of deflection of a magnetic needle, when thus under the influence of a voltaic current, are strictly proportional to the strength of the current or the quantity of electricity passing. Such a needle, therefore, becomes one of the most convenient instruments for measuring or comparing the effective energy of different currents, and forms the essential principle of the *galvanoscope* or *galvanometer*.

When two electric currents traverse two parallel conductors in the same direction, they mutually attract each other, but if the direction of the respective currents is contrary, they repel each other. This was Ampère's discovery, and was made by him shortly after Oersted discovered the action of the current upon a magnetized needle. This action may be readily demonstrated by a simple apparatus known as Roget's vibrating spiral. A copper wire about 0.7 mm. in diameter (No. 22 B. W. G.) is coiled into a spiral or helix of about 30 turns of 25 mm. (1 inch) diameter. Its upper end may be fastened in a binding-screw or clamp, from which it is vertically suspended, in such a manner that the lower end just dips into a small cup of mercury. If a current of from three to five Grove or bichromate battery cells, or an equivalent current from a dynamo-machine, is made to pass through the spiral by means of the binding screw and the mercury cup, the adjacent convolutions of the spiral are traversed by parallel currents, or what is the same thing, by parallel sections of the same current. The spirals, therefore, mutually attract each other, the helix contracts in the direction of its length, and thus the contact with the mercury is broken and the circuit interrupted. Upon the cessation of the current the coils no longer attract each other but tend to separate by their own weight, thus re-establishing the contact between the wire and the mercury; and this action will be indefinitely repeated. The experiment may be rendered still more striking by introducing a magnetized rod of hardened steel about the size of a lead pencil into the interior of the spiral.[1]

It is obvious that all the actions of electric currents upon one another may be multiplied, as in the experiment just described, by using instead of a single wire, a coil of wire, through each convolution of which the same or a similar current is flowing. Hence a circuit formed of ten convolutions of wire would be acted upon by ten times as great a force as a single convolution traversed by the same current.

Upon this fact is based an instrument for indicating, measuring and comparing currents, called the *electro-dynamometer*, which will hereafter be explained.

If a metallic wire be wound in a spiral or helix around a glass tube containing an unmagnetized bar or rod of iron or steel, and an electric current be then passed through the wire, the enclosed bar becomes strongly magnetic. This experiment was first made by Ampère. It is not necessary, however, that the iron or steel bar should be placed in a tube. It is quite sufficient to wind around the bar a copper wire overspun with a coating of silk, cotton or other non-conductor of electricity, in order to insulate the adjacent convolutions of wire from each other and force the current to pass through its entire length. The action of the current by which the magnetism is induced in the iron or steel, is multiplied by the number of convolutions, so that a comparatively feeble current may thus be made to produce a powerful magnetizing effect. So long as the current continues to flow the enclosed bar remains magnetic and exhibits all the phenomena of an artificial magnet, such as the capacity to attract other pieces of iron or steel, and even of inducing magnetism in such pieces when in contact with or in close proximity to itself. Such an apparatus is one form of the *electro-magnet*. If the bar thus endowed with magnetism is of hardened iron or steel it will retain a considerable amount of magnetism even after the current ceases to flow, but if of annealed or soft-iron the magnetism disappears instantly upon the cessation of the current and

1. Atkinson's Ganot's Physics; 10th ed. p. 764.

Digitized by Google

the bar becomes neutral as before, scarcely a trace of remaining magnetism being perceptible.

The power of the electric current to thus induce magnetism in soft iron is, from a practical point of view, its most useful characteristic. It is this quality which renders possible its adaptation to a vast and rapidly increasing number of useful purposes in the domain of science and the arts.

The *magnetometer* is an example of a measuring apparatus based upon this property of the electric current.

4. *Electro-Static Attraction.*—If a piece of glass and a piece of gutta-percha or other resinous material are rubbed smartly together, they will be found to manifest a certain attraction for each other, and it will also be found that either the rubbed gutta-percha or the rubbed glass is capable of attracting any light body in its vicinity. This form of electrical attraction was observed by the ancients, and was perhaps the earliest electrical phenomenon which attracted notice. If a voltaic battery be formed of a large number, for example 500 or 1,000 elements, and has its poles brought into the immediate vicinity of each other without being actually united by a metallic conductor, and a light body, as a pith-ball, be freely suspended from a support in electrical connection with each of the two poles, the respective pith-balls will be found to mutually attract each other. This effect is assumed to be due to an accumulation of positive electricity at one pole of the battery and of negative electricity at the other pole, both being in a static condition. The attraction manifested between bodies thus oppositely electrified is termed *electro-static attraction.*

This attraction is utilized in the construction of certain kinds of apparatus for electrical measurement, such for example as the *electroscope* and the *electrometer*, which are employed to indicate the presence of a static charge of electricity or to determine its potential.

(*To be continued.*)

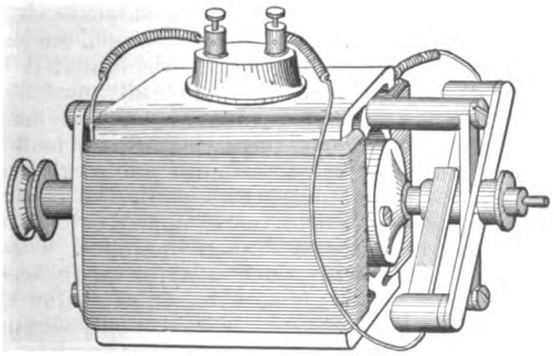
ELECTRICAL MOTORS AND THEIR CONSTRUCTION.[1]

BY JOHN E. CHASTER.

(Concluded from page 128.)

The suggestion was made to me to use for my motor a clumsy imitation of the Siemens armature form, of strips of iron made in the shape of a cross. This was experimentally tested, but with very unsatisfactory results.

I trust that amateurs will be able to construct a motor from my description in a satisfactory manner. When correctly fitted up the motor will be found to be of very high efficiency. The making of the patterns for the castings is very troublesome and perhaps beyond the skill of many amateurs, so that it may be advisable to get the castings made at a regular shop. These should be well carburetted and thoroughly annealed, and if cleanly made will require but little labor in fitting.



The engraving of the motor given herewith is from a photograph taken from the finished machine, and in combination with the drawings already given, will serve to make the construction and fitting quite clear.

1. *English Mechanic* (abridged).

[The directions for the construction of the above motor has awakened considerable interest among our readers, one of whom has kindly furnished details of a similar motor constructed by himself. His description is followed by directions for preparing a cheaper bichromate solution which will be found useful.—EDITOR.]

MOTOR CONSTRUCTED BY E. F. COLE.

The following is a partial description of the electric motor constructed by the writer, which is referred to in letter 33, page 226, of the ELECTRICIAN AND ELECTRICAL ENGINEER. The reader is presupposed to have some knowledge of the subject, as the description relates principally to such parts as may vary somewhat from the usual mode of construction. The dimensions may be obtained from the accompanying cuts which are half size.

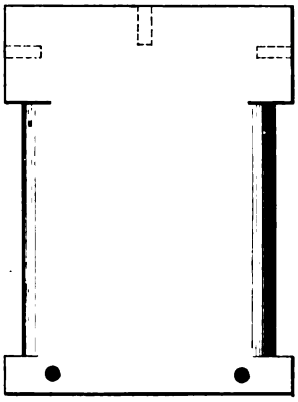


FIGURE 1.

FIGURE 2.

The field-magnet is of cast-iron, of the form shown in figures 1 and 2; figure 1 showing a side, and figure 2 a sectional view of one-half.

Figure 3 shows the form of the armature, which is of *wrought iron*, thoroughly annealed. Figure 4 represents the same after winding, and figure 5 shows a cross-section of the armature and field-magnet. It will be seen

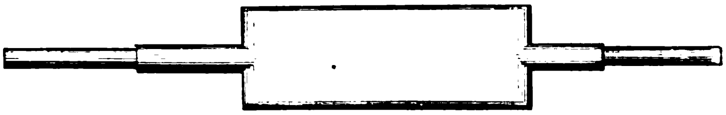

FIGURE 3.

from fig. 5 that the curve of the pole extensions and the circle described by the armature are not concentric; the former forming arcs of a larger circle.

The bearings for the armature may be of any convenient form, providing they are well trued up, and rigidly secured to the magnet. This is quite an important point, as the armature should rotate with the least possible variation. A cap of wood or vulcanite, *b*, fig. 5, may be secured to the top of the magnet, to which the binding posts can

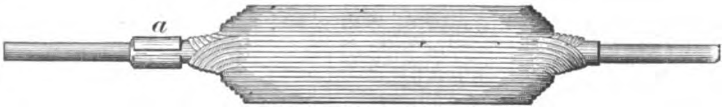

FIGURE 4.

be attached. The armature contains five layers of No. 18 wire (American gauge), the ends of which are attached to the commutator, *a*, fig. 4, in the usual manner. The connection is not shown in the cut.

As the wire is wound on, it is cemented together with shellac or a varnish composed of sealing-wax and alcohol. The field-magnet is wound with three layers of No. 16

Digitized by Google

wire, and the coils of the two limbs so connected that the current will divide between them.

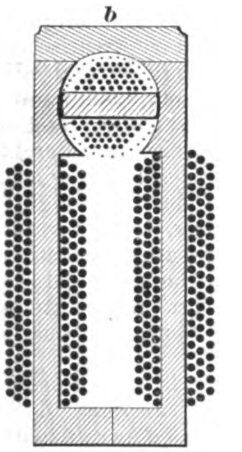

FIGURE 5.

This gives double terminals, one of which is connected with one of the binding posts, and the other with one brush of the commutator, the remaining post and brush being connected with each other.

It is, perhaps, hardly necessary to state that the commutator must be so arranged as to reverse the current when the poles of the armature are within the hollow of the magnet, as in fig. 5.

Thus arranged, the motor is adapted to a battery of six or eight bichromate cells, containing zinc plates 3x6 inches.

E. F. COLE.

ARKWRIGHT, N. Y., July 18, 1885.

A NEW BICHROMATE SOLUTION.

THERE appears to be unusual interest shown at the present time in primary batteries adapted to electric lighting and motors, especially for experimental purposes. As yet, no form of battery discovered possesses so many desirable qualities as the various forms of carbon, actuated by a solution of bichromate of potash. It has now been thoroughly demonstrated by practical experience that the bichromate of soda is in every respect a perfect substitute for the potash, while the price per pound is two cents less. Its principal use heretofore has been as a fertilizer. Not being in the form of a crystal, it dissolves more readily, and does not crystallize on the carbon plates, when the battery is overworked. It has now been regularly used for two months by the Gold and Stock Telegraph Co. in this city for driving the stock printers. About 8,000 cells of the Fuller form of battery are used in this service, forming probably the largest plant of the kind in the world.

The following are the proportions used for the ordinary bichromate solution by Mr. M. Breslin, the chief batteryman, who has devoted much attention to obtaining the best possible results: Three gallons of water, 15 pounds sulphuric acid, five pounds bichromate of soda, making six gallons of the fluid. He believes that by further experimenting he may be able to produce a heavier and consequently a more enduring solution. As the bichromate is the most expensive ingredient in the maintenance of such batteries, the satisfactory performance of a cheaper article should lead to its general adoption. Our readers may be assured that the adoption of this solution by the Gold and Stock Telegraph Co. is the most thorough endorsement that could be given it, and it may be used with confidence in every case where required.

ATMOSPHERIC ELECTRICITY.

BY LUCIEN I. BLAKE, PH. D.

IN the May number of "THE ELECTRICIAN AND ELECTRICAL ENGINEER," the president of the N. Y. Electrical Society has appended some remarks of his own to a paper upon Atmospheric Electricity, presented by myself before that Society. Through absence at the meeting when the paper was read, I had no cognizance of the remarks until they appeared in this journal. Although the theories in regard to atmospheric electricity, mentioned in the remarks, are long since known to scientists to be based upon old experiments demonstrably imperfect and in general incorrect,[1] and consequently need no new refutation, still since the paper is misrepresented, through confusion in the scientific distinction between *convection* and *conduction*, on the part of the president of that society, it is well to call attention to these remarks.

The object of the paper, as stated in it, was not to discuss *all* the theories as to the cause or causes of atmospheric electricity advanced in times past and present, but solely to show, 1st, the general conclusions now accepted as regards the production of electricity by *quiet evaporation* (the only kind of evaporation occurring in nature) and, 2d, *that one of the most plausible existing theories is based upon an erroneous principle.* Hence the charge of "one-sidedness" in presentation is not relevant.

The theory of atmospheric electricity which is proposed in the remarks as satisfactory, is that of electrostatic induction. The earth's negative charge induces electricity in the cloud masses above. We shall see this cannot be a sufficient cause of the immense quantities of electricity in the atmosphere. If the potential at any point in the atmosphere, say even 15 ft. from the earth, is measured by means of Sir Wm. Thomson's water dropping collector, as employed for the last ten years at the Kew observatory, London, and as now employed at Johns Hopkins and Harvard, or even by a Volta flame, the indications will show really the difference of potential between that point and the earth's surface, or will thereby determine the quantity of electricity upon the earth's surface at the place of observation. Now observations show[2] that the variations which occur in the electrical density on the earth's surface are so rapid and so enormous that no other cause than the inductive action upon the earth of the electrified cloud or air masses above is in any way sufficient to account for them. In fog or mist, when according to the remarks, this conducting mass should be negative, it has always been found to be positive. If these observations should be extended over the whole earth, and there is no reason for presuming that they would not indicate everywhere similar fluctuations, the atmospheric electrification, which according to the remarks is the *induced* charge—must enormously surpass the earth's charge,—or the induced exceeds the inducing electrification, which is absurd.

To return to the paper. As regards the production of electricity by evaporation, the subject has been so thoroughly discussed, the errors, due chiefly to the imperfect instruments of early experimenters, such as Volta, Pouillet, Saussure, shown so indisputably by such authorities as *Riess Reibung's Elektricität*, 2, p. 407 & 491, 1853, *Philos. Mag.*, 13, p. 398, 1882, *Wiedemann's Lehre von der Elektricität*, vol. i., p. 240, 1884, the highest and most recent text-book authority in Germany, that it is surprising that a sufficient source here of atmospheric electricity is longer entertained by any minds. Helmholtz, by the way, has never made any investigations upon the production of electricity by evaporation, though so stated in the remarks.

But the most important part of the paper, the *disproving of an hitherto believed natural law*, the president has entirely failed to grasp, because he has confused conduction with convection. The paper does not deal with conduction through vapory matter. That subject is well understood by all physicists. The remarks about the conductibility of watery vapor hence have no bearing at all upon the subject. The paper simply proves that vapor of any temperature ascending from an electrified surface is incapable of being the bearer of any electricity—of carrying any electricity away from that surface with itself. Such a process would be *convection*. Conduction on the other hand, would be the passage of electricity through the vapor. The value of establishing the electrical neutrality of vapor ascending from an electrified surface lies here, in so far as atmospheric electricity is concerned. If we can only account for the original electrification of minute vapor particles in the air, then will be rendered plausible Tait's theory[3] of the

Digitized by Google

increase of potential by agglomeration of these particles into drops to form clouds and rain, according to the law of the dependence of the potential of a sphere upon its radius. Granted the ocean's surface is statically electrified ; granted the electrical *convection* by the vapors ascending from that surface, the electrification of the vapor particles in the air is accounted for, and the enormous increase of potential with the sudden condensations explained. The paper proves the intermediate step of vapor convection which is essential to this theory, as well as to those of Franklin,[4] E. Becquerel[5] and De la Rive[6] is false.

DEATH OF PROFESSOR FLEEMING JENKIN, F.R.S.

Among the eminent scientists who have devoted their best work to the thorough investigation of electricity and its application to useful purposes, perhaps none have left a more satisfactory record than the late Mr. H. C. Fleeming Jenkin, Professor of Engineering in the University of Edinburgh. He had recently devoted considerable attention to electric locomotion, and just previous to his death had been engaged for a short time at London in the development of inventions devoted to that work. He returned to his Edinburgh home to undergo a slight surgical operation, which was followed by blood poisoning, finally terminating fatally on Friday, June 12. He was the only son of Captain Charles Jenkin, R.N., and was born at Stowting Court, Kent, in 1833. At the age of 13 he attended school at Frankfort. A year later he went to Paris and remained during the revolution of 1848, subsequently graduating at the University of Genoa, where he obtained the degree of M.A. His first experience at practical work was at a locomotive shop in Marseilles, which was followed by a three years apprenticeship with Sir W. Fairbairn, of Manchester. He entered the service of Messrs. Newall, at Birkenhead, in 1857, where the first Atlantic cable was then being manufactured. Being entrusted with their principal engineering and electrical work, his future career was determined by his experience while so engaged, and the acquaintanceship with Sir William Thomson, which he formed at that time, contributed materially to his subsequent success. After participating in the manufacture of the Atlantic, Red Sea, and several Mediterranean cables, also in the laying of some of the latter, he formed a partnership with Mr. H. C. Forde in 1861, and engaged in the business of civil engineering at London. It was at about this date that under the encouragement of his friend Sir William Thomson, he became identified with scientific literature, his first paper being on "The Transmission of Electric Signals Through Submarine Cables," which was presented to the Royal Society in 1862. In conjunction with Sir William Thomson and the late C. F. Varley, he became interested in the invention of cable instruments, the patents for which proved extremely valuable. In 1866 (being then a Fellow of the Royal Society) he was elected to the Professorship of Engineering in the University College, London. His most excellent work during his two years occupancy of this chair led to his selection for a similar position with the University of Edinburgh in 1868. In accepting this professorship he was compelled to relinquish his association with Mr. Forde. Being a highly skilled and enthusiastic teacher he soon attracted to his class many bright and able young men, whose subsequent professional success has proved the efficacy of his methods. His mental activity however, did not permit his confinement to the simple routine of his duties as a professor. He became a prominent member of various scientific societies, while his signal ability led to his frequent engagement as consulting engineer and electrical expert, serving also in a public capacity as assessor at the courts.

4. *Mem. Cour. de l'Acad. d. Belg.* XVI., 1843.
5. *Comptes Rendus*, 1856, t. 42, p. 661.
6. *Traité de l'Electricité*, 1858, t. III., p. 190.

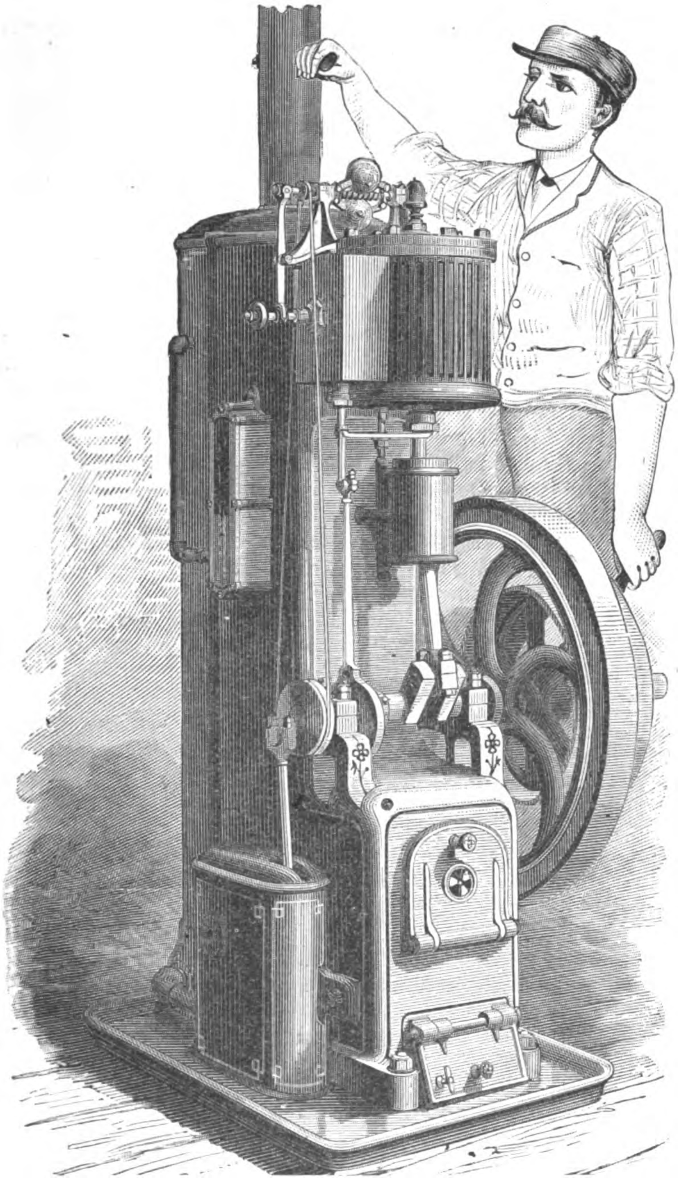
His literary work although quite extensive was by no means confined to electrical subjects. His principal text-book, and the last one, entitled "Electricity and Magnetism," is perhaps the best existing elementary treatise on the subject, and has already passed through several editions and been translated into various foreign languages. Many of his essays were published in the *North British Review*, and among the topics treated by him at different times, were evolution, education, economics and hygiene. He was one of those men of broad intellect, thoroughly known only to his most intimate friends, who, for the most part, were specialists in literature and art, rather than devoted to such subjects as formed the principal occupation of his life. An accomplished linguist, litterateur, critic, metaphysician and sportsman, he appeared equally familiar with almost every subject.

In 1882 he became quite interested in a lecture illustrative of Professors Ayrton and Perry's absolute block signal system, and made a proposition to coöperate with those gentlemen for the development and perfection of a method of overhead electric transportation, to which he ultimately gave the name of "telpherage." This was eventually followed by the organization of the Telpherage Company, of which he was a director, and after a long series of experiments, a practical telpher line was undertaken for carrying 250 tons of clay per week for the Sussex Portland Cement Company. The manufacture of the electric motors, and the construction of the line for this purpose was occupying his attention, when he returned home from London for the last time. In the development of this system his prolific inventive genius was apparent, as was shown by his many patents, which experience taught him were necessary to overcome the many obstacles encountered. Bridge work, hydraulics, methods of mechanically transmitting power, and heat engines were also at various times improved by him. He won many titular distinctions, being an L.L.D. of the Glasgow University, and an honorary member of the Société Professionelle d'Hygiène of Paris. In 1859 he married the only daughter of the late Alfred Austin, who survives him. He also leaves three sons, the eldest of whom, Austin F. Jenkin, has achieved distinction at Trinity College, Cambridge.

THE DAVEY SAFETY ENGINE.

This engine, which is perhaps more appropriately designated the vacuum motor, was invented by Henry Davey, a prominent English mechanical engineer. It is intended for use where hitherto gas and hot air engines have been looked upon with much favor on account of their freedom from the hazard which attends the use of the ordinary steam engine, unless cared for more systematically than is frequently the case. As its principle, although not entirely new, is practically adapted for actual service, and secures absolute safety, the motor deserves careful investigation. While the use of steam is required to operate it, the motive power is derived, not from its pressure in a confined vessel, but from the production of a vacuum by condensation of the steam at ordinary atmospheric pressure. The only function of the steam, therefore, is to expel the air, when upon condensation a vacuum is produced, and the consequent atmospheric pressure moves the piston. There is absolutely no pressure whatever in the generator, and consequently no danger of explosion under any circumstances. Condensation of this low pressure steam is effected by means of a surface condenser, kept cool by water. Where access can be had to an aqueduct water service, the condenser is placed in the upright iron pocket shown in the cut, at the back of the engine. To this a stream of water is led through a pipe from $\frac{1}{8}$ to $\frac{1}{2}$ an inch diameter, according to the size of the engine. The water enters at the bottom and rises to the top, where it passes off through an overflow. In case running water cannot be

had, the condenser may be placed in a wooden tank at any convenient place within a few feet of the engine, to which connections are made by means of pipes. The consumption of water is confined to the amount required to supply the generator—about three gallons per h. p. per hour—which is evaporated, condensed, and discharged in the form of distilled water from a little pipe at the side of the engine. If desirable this water may be saved and permitted to cool, when it may be returned to the tank and used over and over again. Arranged in this way there is no actual consumption of water, and the tank once filled will last for months without a fresh supply. The



THE DAVEY SAFETY ENGINE.

engine is double-acting, a vacuum being formed alternately at each end of the cylinder. The cylinder, piston-head and rod are made of bronze, and require no oiling, the low steam used being moist, and in itself a sufficient lubricant. Another advantage arising from the use of bronze is that in case the engine stands idle for any length of time, it suffers no deterioration from rust. The economy of fuel is considerable, as the quantity of water consumed is less than half that required in running an ordinary steam engine of equal power, while the water is raised to but 212°, instead of 300 to 340°, as in a high-pressure boiler. The comparatively low temperature causes but little precipitation of lime in the generator. The water level is constant and unvarying, the supply being automatically regulated, and even should it fluctuate, no danger can ensue. It has no safety valve, no exhaust, no steam gauge, no gauge cocks, no boiler pump nor injector, most of which devices require careful attention in the ordinary steam engine. Any class of fuel may be used which will go into the fire-box—either hard or soft coal, wood, coke, or cobs; petroleum or gas may be used by a proper arrangement of pipes in the fire box. The cost of ordinary fuel will not exceed one cent per h. p. per hour, and it requires no more attention than a domestic stove. There being no pressure to provide against, the generator is constructed of cast iron, and cannot be readily burned out or caused to leak. It will suffer no injury if allowed to run perfectly dry with a fire burning in the furnace.

Among the advantages claimed for this motor over the high-pressure engine, are the following: Economy in fuel; exemption from injury arising from careless firing; no possibility of explosion under any circumstances; no necessity for skilled attention. Its superiority over the gas engine is that its first cost is only about half as much, while the cost of fuel is but about one-fourth. Its mechanism is much simpler and less liable to derangement. Its consumption of water is no greater, and the air is not vitiated by the discharge of unburnt gas and the products of combustion.

The working parts being in all respects the same as a steam engine, it is equally durable, and the weight ranges from 700 to 1,800 pounds. The motor may be started in from 10 to 20 minutes after lighting the fire. In buildings heated by steam, it may be attached to the radiator in any room, and in such cases, of course, no fire is required in the generator, the engine being controlled by the valve connecting it with the steam coil. They may be run at a speed of from 150 to 200 revolutions per minute, and are at present constructed in sizes from one-half to four h. p. There is no mechanical obstacle to their being made of a larger size, but as in such cases the amount of machinery driven will in most cases require skilled attendance, it is not likely there will be sufficient demand to warrant the manufacture of a larger size. This motor appears to be admirably adapted for small electric lighting plants, experimental laboratories, workshops, and business houses. It is quite extensively used in Great Britain and France, and as its merits become known will doubtless find a large field in the United States, where it is built under license of the patentee, by Chas. P. Willard & Co., of Chicago, Ill.

SPARKING DISTANCE AND DIFFERENCE OF POTENTIALS.

PROFESSOR G. C. FOSTER, read a paper before the Physical Society on the "Difference of Potentials required to give Electric Sparks in Air." The sparks were taken between two brass balls 1.35 centimetres in radius, and the electricity was supplied by a frictional machine. The difference of potential was measured by an absolute attracted-disc electrometer, in which the attraction of the disc was weighed by a balance beam and scale pans. The expression obtained was $v = 102d + 7.07$, where v = the difference of potentials, and d = the distance in centimetres. For distances up to one centimetre this formula held good, and the experimental values agreed very well with the calculated ones. For longer sparks the experimental values fell short of the calculated ones. It also appeared from these experiments that the maximum electric force required for the passage of a spark between the balls decreased as the distance increased. Thus when the distance was 0.142 centimetres, the electric force was 154.76, when 0.497 centimetres, it was 131.66, when 0.9 centimetres, it was 138.57, showing that after reaching a minimum, the force rose again. These results are very remarkable.

AN ELECTRICAL STANDARD FOR MEASURING LIGHT.

The arrangement of an incandescent lamp for use as a standard light for photographic purposes has been the subject of a series of experiments by Thomas A. Edison and his assistant, John Ott. The problem of obtaining a uniform current and a steady light from a variable battery with lamps of different resistances has been solved, and we copy from the *Scientific American*, a description of the apparatus.

During the past winter months the officers of the Society of Amateur Photographers, of this city, undertook to invent or provide some form of standard light which could be depended upon, to be used in testing the sensitiveness of different brands of gelatino-bromide dry plates. It occurred to them that possibly Mr. Edison might devise a uniform electric light, the actinic qualities of which, it was well known, would be invaluable for the kind of work to be undertaken. The strength of the light required was to be equal to one c.p. When the matter was first introduced it was thought that there would be no difficulty in obtaining a means of accurately measuring and controlling the resistance of such a small lamp, if a battery was employed.

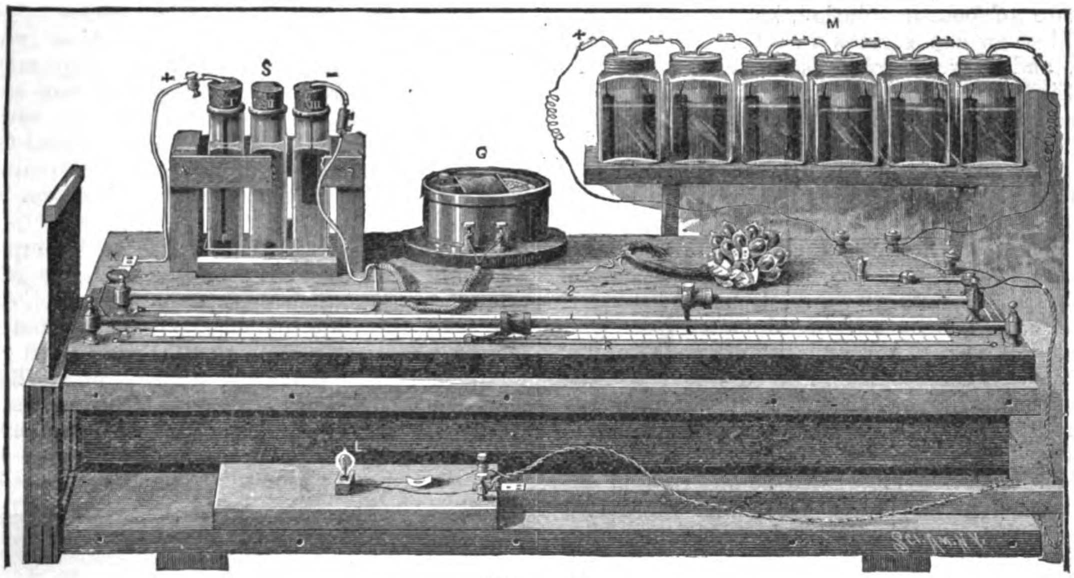

FIGURE 1.

The original plan was to interpose a known resistance in the main circuit with the lamp, which could be varied, and also an ampèremeter or a voltmeter for measuring the variations of the current; but, after a large number of experiments, it was found impossible to make an instrument delicate enough to obtain accurate measurements.

Mr. Edison then turned his attention to the utilization of the electrical compensation balance invented a few years ago by Prof. Poggendorf, which is generally recognized as being the most delicate method of measuring the electromotive force of batteries, and at the same time has the advantage of being entirely free from any detrimental polarization. In this method the currents from two batteries are so balanced by the insertion of a variable resistance that, if a galvanometer is inserted in the circuit, no traces of a current can be perceived.

The arrangement as shown consists of a standard constant battery, a galvanometer, a key, a rheostat or resistance wire in two sections, two parallel brass rods arranged directly above each section of the wire, provided with adjustable collars, which connect the bars to the sections of wire, and a switch, all fixed upon a base which rests upon a photometric testing box. Within the latter, supported upon a sliding board, is the standard electric lamp.

Hinged to this board is a long wooden rod, which when the side of the box is closed, as it is intended to be for actual work, permits the operator to move the lamp at the open end to different distances from the sensitive plate, held in a plate holder slide, shown at the opposite end. The lamp is connected by flexible cords to the binding posts leading to the main battery and one of the sections of the rheostat wire. The apparatus is intended to be used in the photographic dark room. The cell of the standard battery, S, is the standard by which the electromotive force of the Fuller, or main lamp battery, M, is measured. The battery, S, which is comparatively new, is a modification of the well-known Daniell battery. It is so constructed that the fluids cannot become disturbed or mixed through any slight jarring. It consists of three square bottles, 1¼ inches square by 4½ inches high, with a neck ¾ of an inch in diameter by 1 inch long, securely clamped together with metal screw rods at the top and bottom, and held in an upright position by a light wood framework, as shown in the engraving. In the upper part of the adjoining sides of bottles I. and II. is drilled a small hole ⅜ of an inch in diameter, and in the lower part of the adjoining sides of bottles II. and III. are similar holes, all arranged to correspond with each other. A soft rubber washer separates the bottles at the holes, making a water tight joint, and also acting as a support to hold in place a thin film of gold-beater's skin, through which the liquids must pass by the process of endosmose and exosmose, from one bottle to the other.

All of the bottles are filled with a dilute solution of sulphate of zinc; within bottle I. is placed a piece of sulphate of copper about the size of a pea, which changes the solution to a blue color; the copper electrode at the bottom is connected by an insulated wire, which passes through the cork to the back of the key, K. At the bottom of bottle II. is a small chunk of zinc, which collects any deposit of copper, should any pass through from bottle I. In the top of bottle III. is suspended the zinc electrode, which measures about 1½ inches long by ¾ wide and ⅛ thick; its conducting wire as shown passes directly to the galvanometer, G.

It will be noticed this arrangement gives a very constant battery which cannot polarize, as each electrode is completely isolated, and the separation of the bottles with the gold-beater's skin also prevents an easy mixture of the solutions. Each electrode is kept immersed in a solution favorable to retain it in perfect condition.

The main or Fuller battery, M, has been somewhat modified, but consists of a zinc electrode inserted in a porous cup, in which has been placed a teaspoonful of mercury and a dilute solution of sulphuric acid and water. In the glass jar are four carbon rods about one inch square ar-

Digitized by Google

ranged to fit in each corner of the jar, connected by a ring of wire at the top to one conducting wire, which passes out through the top of the cell. The jar is filled with the

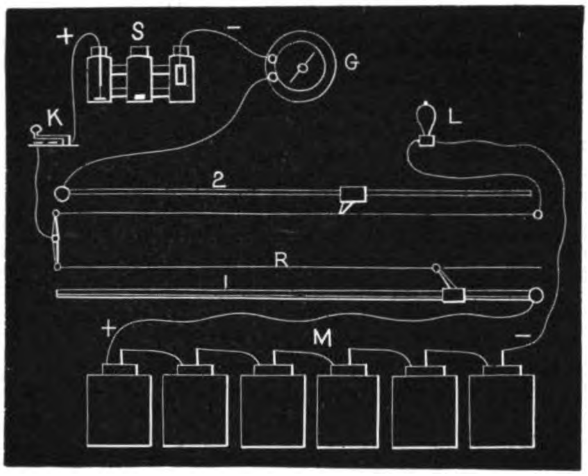

FIG. 2.—DIAGRAM OF CIRCUITS.

usual bichromate of potash solution, known as electropoion. A metal screw cap secures a rubber cover to the top of the jar, and thereby prevents the evaporation of the solution. Six cells are employed, and are plainly seen, located on a shelf at the right, in fig 1.

The amount of resistance inserted in the series is a trifle more than the resistance of the lamp while hot, and consists of a length of 5½ feet of german silver wire $\frac{11}{1000}$ of an inch in diameter, divided into equal sections connected together at one end, as seen in the diagram of fig 2, near the key, K, by a metal link. One section lies upon the millimetre scale parallel with and directly under brass rod No. 2; the other also lies on the board under brass rod No. 1. The section of resistance wire under rod No. 2 is electrically connected thereto by a hinged metal pointed foot and adjustable collar, which may be adjusted to any point on the rod over the millimetre scale, and is secured by a set screw. The position of this collar is never changed except when a new lamp is to be inserted in the circuit. The section of resistance wire under rod No. 1 is electrically connected to the latter by a sliding collar provided with a spring, at the end of which is a grooved brass wheel about $\frac{5}{8}$ of an inch in diameter, which bears directly upon the wire.

In the diagram, fig 2, the arrangement of the apparatus will be seen more clearly. S represents the "standard battery," G the galvanometer, No. 2 brass rod with fixed collar, No. 1 brass rod with movable collar, R resistance wire, which also connects with wire under rod No. 2, K key in the circuit of standard battery, L the electric lamp.

In order to intelligently understand the operation we will detail the two different circuits of the batteries.

The circuit of the Fuller battery, M, is from the positive or carbon pole of the battery to brass bar No. 1, see fig 2, through the collar, spring, and wheel to the german silver wire, R, to the lamp, L, and then back to the negative or zinc pole of the battery. It will be seen that by sliding the collar on rod No. 1, the amount of resistance in this circuit is easily increased or diminished.

The circuit of battery S is from the positive or copper pole through the key, K, to the resistance wire, R, thence through the pointed foot and fixed collar to brass bar No. 2, through the galvanometer, G, and back to the negative or zinc pole of the battery.

In the lamp circuit a switch is inserted for turning the current on and off when testing.

It will be noticed that there is a section of the resistance wire, R (the amount between the end connecting with key, K, and the pointed foot under rod 2), through which the current from each battery flows; and although the current from the main battery, M, has a circuit independent of the galvanometer, it is in this section of wire that both currents are brought into juxtaposition and the electromotive force of the main battery compared with that of the constant battery, S. The variation is at once noticed on the galvanometer, and is easily regulated, as will be hereafter described.

In operating the lamp, the switch in the lamp circuit is first turned on, then the key, K, is pressed, which brings the current of the standard battery, S, into opposition to the current from the main battery, through the galvanometer, G. If the electromotive force of the main battery is too weak, the needle of the galvanometer will be sent to the right of zero a few degrees by battery S; but such movement is at once overcome by diminishing the resistance in the main circuit through the sliding of the collar on rod No. 1 toward the left, in the direction of key, K. As quickly as the resistance is cut out by this movement, so is the needle of the galvanometer forced back to the left until it reaches the zero point; then the batteries are exactly balanced, and the light obtained is equal to that of a standard candle; at this zero reading we have also a constant number of volts of electromotive power.

A bunch of 20 lamps accompanies the apparatus, and may be seen resting upon the base board near the galvanometer. Although all of the lamps may possess the same electrical resistance, they will not emit an equal amount of light, hence in inserting a new lamp it is necessary to locate the hinged pointed metal foot under the brass rod No. 2 at a different point on the millimetre scale, to correspond with the number marked on the label attach to each lamp.

The mode of testing the c.p. of each lamp is to first set the hinged pointed foot arbitrarily at some number on the millimetre scale, then to turn on the switch of battery, M, and gradually slide the wheeled collar from the extreme right hand end of rod No. 1 to the left until enough resistance is cut out to make the intensity of the light from the lamp equal the light of a standard candle, and at the same time to see that the reading of the galvanometer is zero.

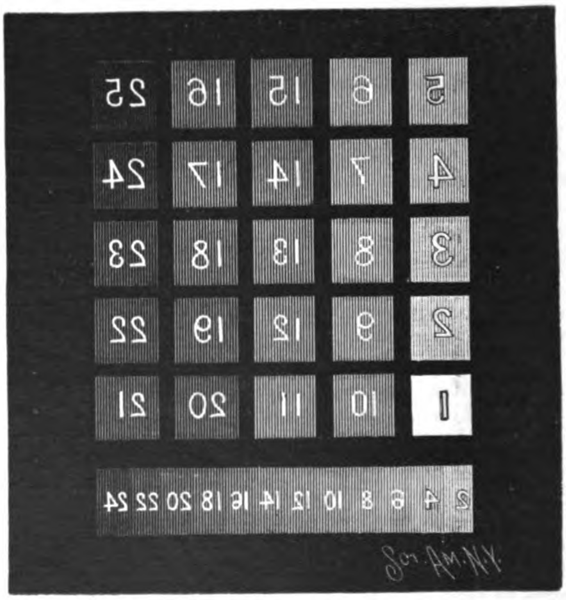

FIG. 3.—SENSITOMETER SCREEN.

The average of a large number of photometric readings is taken to determine the uniformity or the intensity of light emitted from the standard candle.

In view of the differences in the lamps, each one is marked with a special number, which is the separate test, as was shown on the millimetre scale, when it was originally tried, and is to be used when the lamp is put into the main circuit of battery, M, in the manner previously described.

The electrical standard of light thus obtained is far more constant and reliable than that obtained from the standard candle in that all variation of the flame or the uncertainties of the wick are avoided. The galvanometer employed is of the ordinary pattern, having an estimated resistance of about 500 ohms.

As soon as any blackening occurs on the interior of the globe, or even before it, which is due to the gradual destruction of the carbon film from long use, the lamp is removed and a new lamp substituted.

The lamp when employed in making the photographic tests is used but a few seconds at a time, and it is estimated one lamp will, on this account, be good for several thousand tests before the variation of the light will amount to more than one per cent. The simplicity and delicacy by which the resistance is employed to control the current of the variable battery is especially commendable. So delicate is the balance that the resistance of a quarter of an inch of the resistance wire can be read on the galvanometer.

The application of the light in testing the sensitiveness of photographic dry plates may be described as follows: A sensitive dry plate is placed in contact with a Woodbury carbon screen, see fig. 3, such as is used in a Warnerke sensitometer, in a plate holder, and the latter is set into a groove at one end of the testing box, the slide protecting the plate from all light, then being withdrawn, as shown in fig. 1. The electric lamp is then placed so as to be opposite the centre of the screen and 24 inches therefrom. The switch putting the battery, M, in circuit is now turned on, and the light emanating from the lamp is allowed to act upon the screen for 20 seconds; it is instantly stopped by turning off the switch. The sensitive plate is next removed from the plate holder and placed in a developing solution of a given strength for five minutes, and it is then taken out, washed, and immersed in a fixing bath of hyposulphite of soda until the bromide of silver film unacted upon by the light is dissolved out. It is again washed, and when dry is laid film side down upon a piece of white paper. The highest number on the finished negative which can be seen represents the sensitiveness of the plate, and by means of comparative tests the relative sensitiveness of different plates is thus easily determined.

It should be mentioned that the Woodbury screen, fig. 3, is a plate of glass coated with a film of carbon tissue divided into squares, and is made by exposing the sensitized tissue behind another negative screen having similar squares, for a certain number of minutes to the light of the sun, and afterward developed, by dissolving out, with hot water, the parts of the film unacted upon by light. Each square is shaded to be a trifle more dense than its neighbor, and they are distinguished by numbers. No. 1, it will be noticed, is quite transparent, while No. 25 is nearly opaque. The row of figures at the bottom is intended to show in a more compact way the difference in the shading. A sensitive plate showing a reading of 25 will be regarded as having an extreme degree of sensitiveness; and other things being equal, such as freedom from fog in the film, will be excellently adapted for taking instantaneous pictures. One showing 14 would be considered very slow, but excellent for copying or for ordinary landscape work. Nearly two hundred tests have been very successfully made with the lamp, and it forms a valuable addition to the photographic laboratory. In addition to its application to photography, the light may be used for many other purposes, such as comparative photometric tests with other kinds of illuminants. It forms a ready and convenient standard for use in the laboratory, or even for use in gas works, and is an improvement which has long been sought for.

ON THE SIMULTANEOUS DETERMINATION OF THE ELECTROMOTIVE FORCE AND INTERNAL RESISTANCE OF BATTERIES.

BY PROFESSOR W. L. HOOPER.

It is a well-known fact that the fall of potential between points in a closed circuit varies directly as the resistance between those points. This is true even when the resistance includes the seat of the electromotive force of the circuit, as in the electrolyte of a galvanic cell or the armature of a dynamo. Some time ago I devised a method, founded on this principle, of measuring the resistance of batteries (see Vol. III., p. 59, ELECTRICIAN AND ELECTRICAL ENGINEER), but afterwards found I had been anticipated by Kempe. The key that I used has, however, never been described. It is similar to the double key fre-

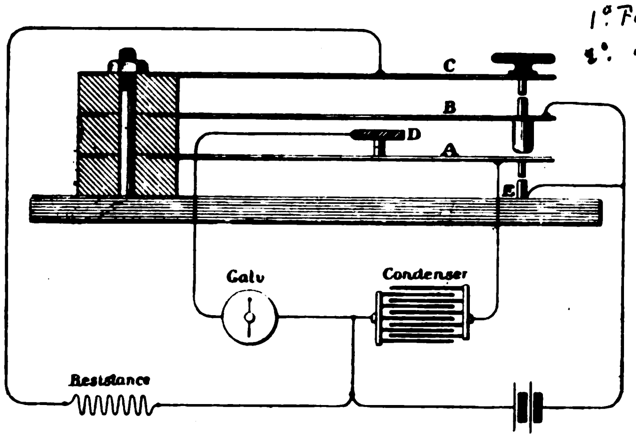

FIGURE 1.

quently used with the Wheatstone bridge, excepting that over the lower arm, A, is a cross-bar, D, in metallic contact with it when the arm is in its normal position. In use, one terminal of the battery is connected to the pin, E, the other to a condenser; the same terminal of the condenser is connected through a delicate reflecting galvanometer to the crossbar, D, the other terminal to the lower arm, A. When the key is pressed, the condenser is charged; when released, the condenser is discharged through the galvanometer, from the throw of whose needle the electromotive force of the cell may of course be calculated.

The poles of the battery are then connected through a known resistance, best approximately equal to the resistance of the battery, to the two upper arms, B and C, and the difference of potential again observed by pressing the key. The known resistance must of course include the contact resistance between B and C.

If E is the electromotive force of the battery, E' the difference of potential between its poles when the circuit is closed, R the internal resistance, and V the known external resistance, we shall have: (see note above)

$$\frac{E}{E'} = \frac{R \times V}{V}$$

whence R is easily calculated.

As the circuit is only momentarily closed, there is no time for polarization to occur; and as the condenser, excepting when the key is pressed, is always short-circuited through the galvanometer, there is no chance for a residual charge to accumulate in it. I have found no method so expeditious and trustworthy; indeed, by it the resistance of a cell is obtained almost as quickly and with but little less accuracy, than that of a coil of wire with the Wheatstone bridge.

Every one who has had much to do with batteries has of course noticed the more or less rapid decrease of current from a cell coupled up with a small external resistance. It has been usual to attribute this decrease of current to the opposing electromotive force of polarization. Now, the current in any circuit is a function of two variables—

Digitized by Google

the electromotive force and resistance; and in a battery circuit, when the external is small, variations of internal resistance may be nearly as effective in changing the current as variations of electromotive force itself. In certain cells with which I have experimented, I have felt sure that the decrease of current was not altogether due to polarization, but partly to altered resistance, owing to changes in the composition of the electrolyte. So far as I know, no method has been devised that would enable one to simultaneously determine both electromotive force and internal resistance of a battery in action, and that, too, without appreciably interfering with the arrangements of the circuit. I have, therefore, sought to devise a method that would enable one to obtain a practically continuous record of the electromotive force and internal resistance of a battery during the whole or any part of its entire life.

For this purpose I added another arm to my old key, and placed a cross-bar over each arm, four in all. The key is connected to battery, known resistance, two condensers, and two galvanometers, as shown in figure 2.

On pressing the key, D separates from I, breaking connection between the condenser and galvanometer for obtaining the difference of potential between the poles of the short-circuited battery. The upper arm, D, coming in contact with C, connects the battery and condenser, which receives a charge, but this circuit is at once broken by the separation of C from H. C, descending, comes in contact with the hard rubber button on B, and depressing it, opens the battery circuit through the known resistance. The lower arm, A, is next engaged, and the circuit between the galvanometer and condenser for measuring electromotive force is broken by A leaving the cross-bar, E; the condenser and battery are then connected through K. As the key returns to its normal position, the condenser is discharged through its galvanometer, the resistance circuit again closed, the other condenser once more momentarily connected with the shunted battery, and finally discharged through its galvanometer. The whole operation is completed in a small fraction of a second. Both galvanometers employed by me are Thomson's reflectors of about 6,000

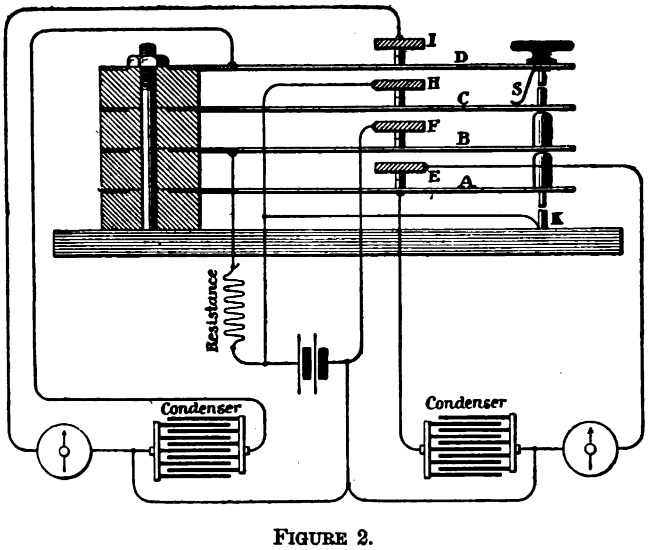

FIGURE 2.

ohms resistance, and are placed 8 or 10 feet apart. The condenser battery and key are usually on the table in front of one of the galvanometers. Two observers are, of course, required. The galvanometers are usually so adjusted that one volt gives 200 or 300 divisions on the scale; this renders the computations much simpler. It would also be well to have the known external resistance some even number of ohms or tenths of an ohm.

A curious difficulty was encountered at first in the use of this key, when it was found that the condenser attached to the upper arm received variable charges for the same difference of potential. After some study and experimenting, the cause of these discrepancies was discovered. It has been explained that the condenser is thrown into circuit with the battery by the upper arm coming in contact with that below it. Now, as the arms are tolerably rigid, it happens that the interval of time between the contact of the two and the separation of the lower, C, from its cross-bar, H, is very short. Hence, as the condenser used was a large one—about 1½ microfarads—there was seldom time

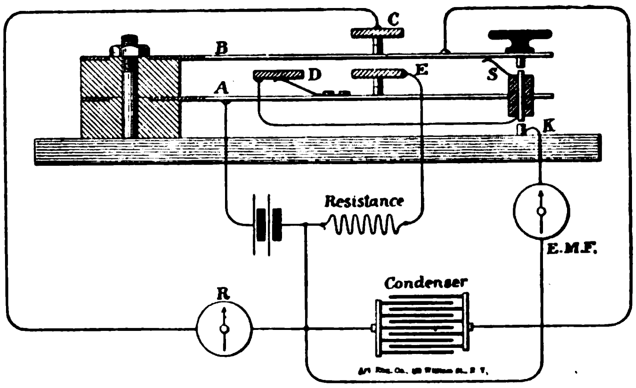

FIGURE 3.

for it to become fully charged. This failure was particularly noticeable with the small standards of electromotive force, the Clarke and plaster of paris Daniell. A piece of watch-spring soldered to the upper arm (as shown at S), so that contact between the two arms was made some time before the lower began to be pushed down, completely remedied the evil, and no further difficulty from the key has been encountered.

Mr. F. S. Pearson, a student in the laboratory, has devised a key necessitating the use of only one condenser, as shown in figure 3. Its action is as follows: The upper arm, B, descending meets the spring attached to the insulated platinum rod at S, which connects the condenser and shunted battery through the cross-bar and spring at D. The spring at S merely serves to obviate the time difficulty mentioned in connection with my key. The condenser now becomes partly charged, and on the battery circuit through the known external resistance being broken at E by the descent of A, the condenser takes its full charge. As the lower arm, A, descends still further, connection between the battery and condenser is broken at the spring, D, and on connection being made between K and B, through the pin, S, the condenser is discharged through the galvanometer, E.M.F. On the return of the arms, connection between the condenser and battery is first established, the condenser taking its full charge; but immediately the resistance circuit is established at E, and the charge of the condenser falls accordingly; connection at S is then broken, and finally the condenser is discharged through the galvanometer, R, from whose deflections the resistance of the battery is calculated.

I append a set of observations with each of two different cells, the Grove and the Orne (bichromate). The known external resistance was in each case .714 ohm. The first column gives the times from the instant of closing resistance circuit, the second and third the deflections of the galvanometer E. M. F., and the volts corresponding to those deflections. The fourth and fifth columns give the deflections and corresponding difference of potential for the other galvanometer. The sixth column gives the deduced internal resistance of the battery for the instant of observation:

The above are specimen observations. In general I may say that every cell has its own peculiarities, from the shape of whose curves for E. M. F. and R the cell may usually be recognized. Thus, the curves of the ordinary bichromate cell show at first a rapid, then a gradual falling off, of E. M. F.; and at first a marked decrease, then a gradual increase, in R. The Leclanché cell resembles the bichromate as far as E. M. F. is concerned, but R in this cell remains nearly constant.

Physical Laboratory of Tuft's College, June, 1885.

THEORY OF MODERN ELECTRIC MACHINES.

BY J. ASHER.

The action of electro-motors and dynamos can be explained by known laws of electric currents. Law 1. Parallel currents which flow in the same direction attract each other. Law 2. Parallel currents which flow in opposite directions repel. Law 3. Two currents which *both* tend either towards or from the same angle attract. Law 4. If one current tends *towards* and another *from* the same angle they repel.

An illustration of law 4 is found in Gore's experiment, which is described in Cazin's work on heat. Two small copper rails are placed parallel and a short distance apart, that a copper ball may roll on them. One terminal of a battery is connected with the right end of the first rail, and the other terminal to the right end of the second rail. The ball rolls from the ends to which the wires are joined. Cazin says the current heats each rail beneath the ball, causing an elevation, which determines the motion. My explanation is different. The motion is caused by the repulsion of electric currents, as in law 4. The current flowing from the battery along the rail tends *towards* the angle where the ball meets the rail; the current passing through the ball tends *from* the same angle. Again, the current flowing through the ball tends *towards* the point where the ball meets the second rail, then tends *from* the same point on its way along the rail towards the battery. A repulsion of the current flowing through the ball is caused by the current in each rail. A small wheeled carriage will roll along in the same way.

Barlow's wheel rotating between the ends of a magnet by the action of a current flowing from centre to circumference, or *vice versa*, has been thought the simplest rotary electro-motor. Now, it is not generally known that the wheel will rotate without the aid of a magnet if the current deviates in the plane of the diameter from the direction in which it flowed on meeting the circumference. This is another illustration of law 4. The ball on rails is the simplest electric locomotive. The rotating disc is the simplest stationary rotary electro-motor. We get little power from these, for we have but one *ply* of the current.

The action of a small Gramme machine used as a motor is explained as follows:—The armature is an iron ring wound in sections with insulated wire. The ring shields a current traversing the wire within from the action of the currents of the magnet. Were the ring of diamagnetic material the action exerted by the magnet on the current passing through the wire covering the exterior of the ring would be partially counteracted by its influence on the current flowing along the wire inside the ring. A permanent magnet may be considered a system of electric currents, according to Ampère's electro-dynamic theory. The resultant of these currents in a straight magnet surrounds it at the surface in the middle of its length. The resultant in a **U** magnet is between its limbs, and some distance from their ends. Figure 1 represents a small Gramme machine. The permanent **U** magnet is provided with curved iron pieces near the ends, which nearly enclose the armature.

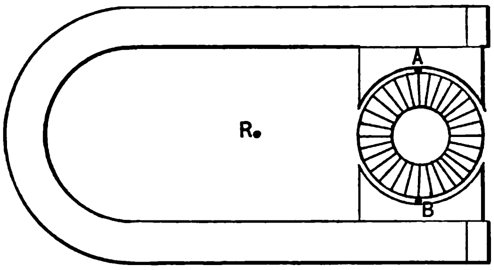

FIGURE 1.

These pieces cause the resultant to have a position nearer the ends. The resultant of the ampère currents in the magnet is at R, and is a straight current flowing from the reader if the upper limb is, as I suppose, a north seeker. The wire covering the exterior of the armature's upper half is traversed by a current entering at the commutator which is not shown. The wire covering the exterior of the lower half is simultaneously traversed by a current flowing in the opposite direction. Let the resultant current passing along the exterior of the upper half be supposed to act at one point, A, as a current indicated by the dot, and flowing towards the reader. Similarly let the resultant current flowing along the wire covering the exterior of the lower half be supposed to act at one point, B, as a current indicated by the dot at B, and flowing *from* the reader.

Now, since B and R are parallel and flow in the same direction, that is, from the reader, the current R attracts B. And because A and R are parallel and flow in opposite directions R repels A. Thus the armature has a tendency to rotate in the same direction as the hands of a watch. The commutator and sections of wire on the armature are so arranged that the resultants, A and B, remain nearly stationary in relation to the magnet. Each resultant of the armature is like a dog on an endless tread motor. The animal ever moves, but never advances. In the larger Gramme machines the axis of the armature is parallel to the axis of the magnets, of which there are two placed end to end. In a machine of this kind there are two curved resultants for each magnet. The action of these upon the current traversing the ring is a case of laws 3 and 4. The resultant of the current on each half of the armature is attracted by that part of a resultant of the magnet which tends either towards or from the same angle, but it is repelled by that part which tends in a different direction. These machines have electro-magnets instead of permanent magnets. The resultants are between the limbs of the magnet.

Siemens's machine has two electro-magnets, end to end. The armature rotates between curved iron extensions in

Digitized by Google

the middle. The axis of the armature is at right angles to that of the magnet. The armature is an iron cylinder wound lengthwise. The right resultant of the double magnet attracts one resultant of the armature and repels the other. The left resultant of the magnet attracts the other resultant of the armature and repels the one. Is iron essential in the armatures of machines of the Siemens type, such as Weston's, Edison's and others? It would be interesting to try one of these machines with a wooden armature. It would not heat, and it would be *light*.

The Meritens motor has a magnet in the form of a wound ring which entirely surrounds the armature. The magnet has two resultants. The armature is a wound Pacinotti ring similar to the Gramme. The resultants of the magnet act upon those of the armature.

The Griscom motor has an annular electro-magnet like that of Meritens. Within this electro-magnet rotates an armature of the early Siemens type. It is an iron cylinder with a wide, deep groove on each side, in which wire is wound. The motor is shown in figure 2.

R is the annular electro-magnet wound on its right and left sides. A portion at the top and bottom is bare, as shown. The armature is shown within the ring. The iron ring shields the armature from the action of the current flowing along the wire on the outside of the ring. Could this wire act it would tend to rotate the armature in the opposite direction. The resultants of the electro-magnet are at A and B; those of the armature at C and D. Suppose A flows from and B towards the reader. Also suppose that C flows towards and D from him. A repels C and B repels D, because A and C are parallel and flow in opposite directions, and because B and D are parallel and flow in opposite directions. This repulsion continues until the armature has passed through about 90°, when A will attract D and B will attract C, because the current D flows in the same direction as A, and C flows in the same direction as B. This action continues until the armature has passed through 90° more; C is then as near to B as possible, and D is as near as possible to A. There is a dead point here, and another when it performs the next half-revolution. After starting, the momentum suffices to carry the armature over the dead point, the current being reversed in the armature, by means of the commutator, just as it approaches the dead centre. In the figure the armature rotates in the same direction as the hands of a watch.

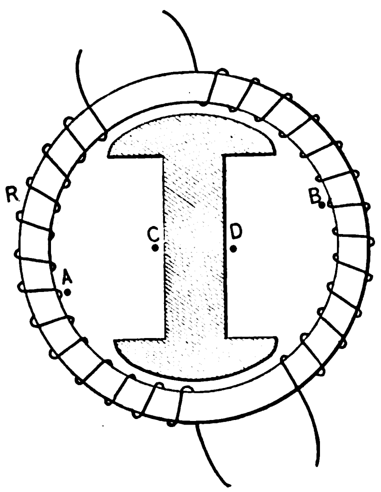

FIGURE 2.

The generation of electricity by machines such as those of Gramme and Siemens may be explained by the laws of induced currents in a conductor moving towards or receding from an electric current. Law 1. When a wire approaches another parallel to it through which a current flows, a current will traverse the moving wire in the opposite direction to that in the other. Law 2. When the moving wire departs from another parallel to it, through which a current is flowing, it will be traversed by a current which flows in the same direction as that in the other wire. Law 3. If a wire, A, conveying a current be caused to move in a certain direction by the action of another current traversing a wire, B, then on moving A in the same direction when it is not connected with a generator a current will traverse A in the opposite direction to that in which its former current flowed. Law 4. On moving A in the opposite direction a current will traverse it in the same direction as that of A's former current. Laws 3 and 4 include laws 1 and 2, but they also apply to cases of angular currents. Laws 3 and 4 explain the action of the larger Gramme machines when used as generators of electricity. In figure 1 let us suppose that the armature is rotated in the opposite direction to the hands of a watch; the wire forming the exterior of the upper half constantly approaches the resultant ampère current at R; hence the wire on that half of the armature will be traversed by a current opposite in direction to that of R. Also, since the wire on the lower half constantly recedes from the resultant R, it will be traversed by a current in the same direction as that of the resultant R. Now, the commutator arranges these currents so as to reinforce each other in the external circuit. In ordinary dynamos a large electro-magnet is used. The ampère currents in the electro-magnet cause the machine to generate a current in the armature wire immediately when set in motion; then a portion of this current passes through the wire on the magnet, and greatly increases the force of the resultant R. I speak of ampère currents in the magnet of a dynamo even when the machine is at rest, for there is always some residual magnetism in iron after having been rendered magnetic.

In explaining the action of these machines I have made no use of the terms "poles" and "lines of force." Ampère's beautiful electro-dynamic theory of magnetism should be constantly kept in the mind of the electrician. The same applies to his laws of the action of currents on each other. These, together with the fact that iron shields an electric current from another on the other side, have not only enabled me to explain the action of any dynamo or motor, but they have also been the means of my inventing several electro-motors and continuous current dynamos without commutators. This result only a few years ago was deemed utterly impossible. Ampère's electro-dynamic theory and laws of attraction and repulsion of electric currents leads me to believe that a continuous motive power can be obtained from permanent magnets. The law of conservation of energy would not be broken if this proposed machine be found to work. The molecular motion in the magnets would be diminished at the same time as motion of the mass occurred, the sum of energy in the universe remaining precisely the same. Those magnetic motors would be universally used in clocks and watches, no winding being required.

COLDSTREAM, Ont., Canada, July 6, 1885.

TECHNICAL JOURNALISM.

BY RALPH W. POPE.

TECHNICAL journalism is the natural outgrowth of industrial progress, and contributes largely to that development of science and invention which has been characteristic of the nineteenth century. While the more important discoveries are eagerly sought out and made public by the enterprise of the daily press, the quiet workers who by their skill and ingenuity patiently labor to bring their experiments into practical form, may have toiled for years in comparative obscurity.

Such men must necessarily keep thoroughly abreast of the times, at least so far as concerns their particular line of investigation, and to them the technical journal is indispensable. It must indeed be a stupid periodical which in the course of the year does not bring them information of far greater value than the price of subscription. Such knowledge is therefore a necessity, rather than a luxury. While we may derive a certain amount of satisfaction from perusing our favorite daily, it is the technical journal which brings to its supporters the bread and meat of every day life. Its field is constantly broadening while bright minds are continually on the look out for opportunities previously neglected. While the type founders and printers have long been represented, it was not until re-

Digitized by Google

cently that the actual makers of a newspaper, the editors, reporters and contributors, were enabled to read a weekly devoted to their own interests. It is to such a journal that we must turn, to learn the methods of the craft, and it is there we find that the great editor is not always the just and unprejudiced man which his followers are led to believe. In its advice to writers seeking employment, the *Journalist* says: "Give particular attention "to the style of the paper and the hobby-horses of the "editor. Every paper has a weakness. The editor, for "instance, may own a lot of gas stocks. If you know this, "anything pitching into the electric light would be particularly desirable. . . . . Statistics are often good "things to furnish. They are hard to cut down, and "the editor rarely knows anything in regard to them."

The frequent inaccuracy in the minor details of ordinary newspaper work was recognized as long ago as Lord Byron's time, else he would not have replied as he did to the query—"what is fame? To be killed in battle and have one's name spelled wrong in the despatches."

Even in the limited experience of the writer, he once figured in the New York *Sun* with great particularity of street, number and business position, as the husband of his brother's wife, an error which was perpetrated with such exact accuracy of other details that its origin still remains a profound mystery. Such mistakes are the more readily excused because of the haste with which material must be collected and prepared. There is, however, another class which are more properly blunders arising from the ignorance of writers upon the subject they attempt to elucidate.

The reporter who described an accident at Jersey City in which a train plunged through the station and the locomotive went off the wharf, gave as the cause, the failure of the "backing" brake. Had he been more familiar with railway mechanism, he would have known that while a brake may be used to stop a train, the engine must be reversed to back it. What he doubtless overheard, was that the "vacuum" brake failed, as was really the case. It was another scribe, doubtless more familiar with atmospheric exhaustion, whose practical training secured him a position on the *Herald*. This genius examined an East river steamboat after an explosion, and discovered a vacuum in her cylinder *six feet long*, which had been broken into seven pieces! Scientific accuracy can scarcely be hoped for in such cases, but when we read in a description of a boiler explosion that "the path taken by the boiler was immediately followed by ourselves," we naturally infer that the reporter was blown up as well.

It may be too much to expect that these details can be carefully watched, as it is well known that but a small minority of newspaper readers will detect such errors, unless they are personally familiar with the subject or incident. It is when our metropolitan dailies venture outside of their province, that they should exercise more care in the preparation of their matter, or at least refrain from dictating the exact course to be pursued by others. It is a common saying in press circles that every man thinks he can run a newspaper. It is also apparent that every editor knows how to run other people's business as well as his own. In the palmy days of Napoleon III. the modest leader of the New York press at that time, would occasionally intimate that if Louis Napoleon would take the advice of the *Herald* many of the difficulties which beset him might be avoided. Whether his eventual downfall could be ascribed to his obstinacy in this respect, is a question for the historian who is more familiar than I am with the mysteries of French statesmanship.

It is frequently the case that under the guise of scientific phraseology a newspaper may cause at least annoyance, and perhaps injury by gross exaggeration or a misstatement of facts. A recent case which was particularly atrocious, was that of the *Evening Telegram*, in which an attempt was made to show that from an artistic and engineering point of view the Bartholdi Statue of Liberty is a failure. Imagine the assurance of a critic of this character, in pointing out to an educated engineer, such as we may presume General Stone to be, that the truss-work was not properly planned. Perhaps it was not, but why should it be left to a *Telegram* reporter to point out technical defects in a work of this character? He then undertakes to prove that in the joining of the iron framework to the copper plates of which the statue is formed, electrical action must subsequently ensue, which will ultimately destroy the metal at such points. With equal foresight many other dire evils could be predicted which *might* occur if proper precautions were not taken to prevent them. Fortunately the animus of this remarkable display of newspaper science was thoroughly understood by the public, and the proper allowance made for these extraordinary criticisms. Similar cases arise, however, in which the motive of the attack is more obscure, when the pernicious influence may consequently be more effectual.

The crusade of the press against the overhead wires is an example of the manner in which the people may be incensed against a minor evil, while more imminent dangers beset them on every hand, that remain comparatively unheeded. For years the law has recognized the necessity of regulating the construction of buildings, the testing of steam boilers, the inspection of steamboats, and the licensing of engineers and pilots.

We have had a cycle of falling buildings in this city and vicinity within a few weeks; a reckless builder has been sentenced to prison and quiet now reigns, the subject being considered stale. No anxiety is manifested in the daily press regarding the thousands of steam boilers "underground," many of them in charge of engineers (?), who are also expected to serve as porters, or men-of-all-work in their respective establishments. Among technical papers the *American Machinist* has frequently alluded to the various mechanical death-traps which pervade the community, a recent instance being its reference to the numerous excursion boats which daily ply our harbor in every direction; many of these steamers are crowded to their utmost carrying capacity, in open violation of the laws which are supposed to protect the people from the avaricious and unscrupulous owners who risk human life, that dollars may be gained. The masses, however, are neither scientific nor mechanical, or if they were they might not be influenced by the opinion of a technical journal, consequently its reasoning, however weighty, is of no avail, because it is misplaced. While those who read its columns may be interested for the time being, there appears to be no manner in which the evils pointed out may be eradicated. The necessary laws exist already, but they are apparently not enforced excepting perhaps for a brief period under the stimulus of some appalling disaster. In a few days any further reference to it is overwhelmed by the later intelligence of perhaps a more serious calamity.

One of the gravest drawbacks to the influence of a journal, is the question as to the honesty of its opinions; in fact, its reputation. It is here that the technical journal finds its path continually beset with thorns. The interests of its readers demand that they shall be enlightened on the merits of new inventions, processes and materials. They do not care to learn from John Smith that in his opinion the Smith dynamo will supply more Smith lamps per h.p. than the dynamo of Jones. Neither do they hanker after Jones's remarks on the Smith machinery. If, however, they have confidence in their favorite electrical journal, they might be glad to obtain, if they could, an official editorial decision.

It is right here that the sphere of the technical journal must be bounded. It should offer a fair arena for the statement and elucidation of facts and theories, by those who profess to understand them, under their own names, which, if well-known, carry with them the necessary weight; if not, the reader must judge from the article itself

Digitized by Google

whether the author probably understands his subject.

It is often the case that the technical journal, acting solely in the interest of its readers and without reference to its advertising columns, publishes descriptive matter which is supposed to be beneficial to the inventor, manufacturer or vender of the article in question. It is too frequently understood that financial inducements are offered to secure what is erroneously considered an endorsement of the article, when, in fact, no opinion of its merits is advanced.

Having in view the fact that the mission of the technical journal is to instruct, inform and please its readers, the editor should certainly reserve the right to give a favorable opinion if he so desires, but not without careful investigation. His reputation is to a certain extent his capital, and should therefore be guarded with equal consideration. No allotment of stock or admission on the ground floor of a new enterprise should be allowed to bias his judgment, neither should he by his supposed influence lead others to embark in questionable enterprises.

We have in mind various schemes which have been boomed by different daily papers. Possibly in some cases such advocacy has been paid for, but if not, the desired result was attained by taking advantage of the technical ignorance of the staff, and thousands of readers were misinformed if not duped.

A recent instance is that of the Hathaway printing instrument for the introduction of which capitalists are now being invited to invest. It was announced through the medium of various newspapers that the introduction of this machine was to create a revolution in telegraphy, superseding not only the ordinary Morse instruments, but the telephone as well. The facts are that this machine is a very inferior printer, by no means equal to those in actual use 25 years ago. The only patentable features about it are of no practical value whatever.

At the very outset of the electric lighting business in this country a panic in gas stocks was precipitated by the wildest predictions regarding the future of the new light, which was to be produced at so low a cost as to ruin existing gas companies. There was no foundation for such assertions, but many people were led to sacrifice excellent securities without any better reason than that the newspapers prophesied the final overthrow of gas monopolies. This was seven years ago, and the smile of the present holder of gas stocks is broader than that of most electric light owners. Investors in Keely motor stock were not allured into their present holdings by the representations of technical journals. There has never been an exhibition of the Keely apparatus which really warranted an extended newspaper notice. The whole affair has been brought into notoriety by writers who were not sufficiently versed in science or mechanics to detect its fraudulent nature.

It certainly appears as if would-be investors in questionable enterprises of this character should endeavor to familiarize themselves with the "state of the art;" either by continued perusal of journals devoted to such subjects or else by the employment of trained experts, whose opinions are entitled to weight. A purchaser of real estate would be considered lacking in judgment, unless he engaged competent counsel to search the title. A similar prudent course should be adopted by those who propose to secure an interest in inventions which are not in their line of business.

In pursuance of my subject I have been led to digress somewhat in order to show not only the importance of technical journalism in its relation to the general public, but also to point out the shortcomings of the daily press in its treatment of special subjects.

That this state of affairs can be improved by careful editing is shown by the successful manner in which the respective hobbies of different editors are treated in their columns. No doubt the gradual development of the modern newspaper, whose field is the world, will eventually lead to the organization of a staff which will embrace not only base-ball and billiard experts, but trained scientists and mechanics. The mission of the technical journal will not then be ended however, but its opinions will be entitled to more respect, and its journey to the waste basket less rapid and impetuous.

TARDY ADOPTION OF RAILWAY IMPROVEMENTS.

Railway inventions secure adoption very slowly, though this is because of obvious reasons and is really very fortunate for every one but inventors. Looking back over the years, we remember that long after the Miller platform had proved itself invaluable, and was largely in use, one of our greatest trunk lines still coupled its cars with link and pin, and endeavored to render the transit of passengers from car to car less dangerous and unpleasant by keeping a short plank across the ever varying gulf between the swaying cars.

The air-brakes, too, were looked on by many of the older eastern roads as a new-fangled western device of doubtful utility, and, till appalling accidents compelled, few of the New England railroads had condescended to adopt them, and to-day those self-same roads find a hundred reasons why they should not adopt a uniform system of signals which has met the approval of a large majority of the railroads of the country.

Talk of insular prejudice! Why, ten years ago nearly all our railroad men scouted the idea of track signals other than a red flag or a ball hoisted on a pole. The complicated system used in England might do for John Bull, they said, but it would never be used here. To-day our principal railroads have not only adopted those very signals, but have even improved on the English block system. Now, we have signals at short distances apart which indicate to the engineer with unerring certainty whether the track is clear to the next signal ahead, and which he is otherwise forbidden to pass. These signals are worked by the power of electricity, called into action by the passage of the train itself and depending on no human agency Their automatic action is most interesting to watch. You may be standing near one, no train within sight or hearing. Presently you hear the distant rumble or see the puffs of steam that indicate the approach of a train. As it nears the signal, you see the red disc fall, or the vane of lattice bars revolve, in time for the engineer to note its action. He sees it change and knows at once not only that the track ahead is clear, but that till he has passed the next signal ahead, this faithful signal will forbid the passage of a following train. You wait and watch as the train disappears, and soon the red disc moves, or the lattice bars revolve back to their former position, and you know that the train has safely passed the signal ahead. But this is not all. If the continuity of the track be broken by a rail removed for repairs, or if some straying cow has laid down on the track for a contemplative chew, the signal gives warning of the obstruction, and to fill the measure of its fidelity, if itself inoperative, it displays the warning signal of danger. Yet another purpose is served by electric signals. At level crossings and at stations a gong is made to ring when a train approaches within a certain distance, and the continuous ringing says clearly and unmistakably, "train coming, clear the track."

But the most perfect of signals can only call attention to some fact, and so long as the element of human vigilance is required to note them, so long shall we remain liable to accidents arising from human infirmities.

The English system of connecting and interlocking switches and their signals, in such a manner that one man controls the action of many without moving from his box, and by which the setting of a switch for a certain movement of a train holds all others till that movement is completed, has already been adopted at some of our larger stations, and seems likely to be gradually adopted with the inevitable increase of traffic.—*Railway Review.*

THE CONSTRUCTION OF LINES FOR ELECTRIC CIRCUITS.

BY THOMAS D. LOCKWOOD.

(Continued from page 256.)

A novel but valuable idea has recently been advanced by Mr. E. T. Gilliland in the suspension of aerial cables, and it is thought well to advert to the same here. It is to provide a clip with stirrups like that shown in the figure below, one of the stirrups being open to one side and the other to the reverse side, and having two sleeves (or hooks if preferred) for the accommodation of suspending or leading-in wires.

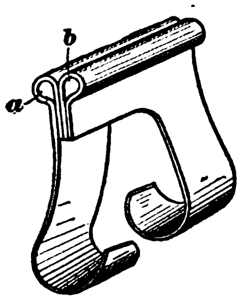

FIGURE 21.

It has been found in practice, particularly in certain districts, that the suspending wire becomes corroded so as to be unreliable, by the action thereon of the gas-laden atmosphere, and when such is the case the entire cable has had to be lowered, before a new suspending wire could be put in. By using the clip shown above and when the cable is first suspended, providing two wires from end to end, each passing through one of the clip sleeves *a* and *b*, such an inconvenience is avoided.

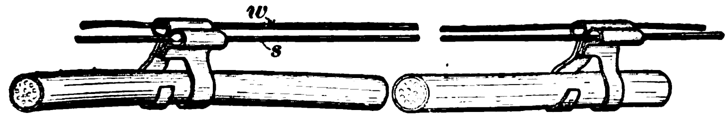

FIGURE 22.

Both of the wires *w* and *s* may be strong suspending wires, or one only may be a suspending wire and the other a light pulling-in-wire which may be of brass, phosphor-bronze or such non-oxidizable metal or alloy.

It is evident that by the use of this device whenever it is found that the supporting wire is corroded so as to be unreliable, a new one may be then attached to the other wire and drawn in; while a new drawing-in-wire can then similarly be attached to the corroded sustaining wire, so that when it is drawn out, it will draw after it a new drawing-in-wire, so that an alternative wire is at all times in place and ready for use. A little screw sleeve with tapered ends is used to connect the wires while drawing in, so that they will not stick while passing through the sleeves.

EARTH TERMINALS.

This, though frequently the last subject to be considered in building an electric line, can never be regarded as the least important. It is of course essential to the working of our circuit that it shall be completed in some way either by a return wire or by the earth. For long telegraph lines there need be no question as to which mode is the preferable one. Twice the length of line wire involving nearly a double cost for material, is a sufficient consideration, even if there were no other, to determine for us that such a line should be terminated at both ends in the earth. It is also a fact that long lines (if the earth connection is properly constructed) have a much smaller total resistance with an earth return, than they would have with a return wire, and hence are operated with a much greater degree of economy. If the earth connection is not well made, satisfactory working is absolutely impossible, and until rectified, the operation of the line will always be both difficult and expensive. Experience so far, has proved that although an earth return is the best for telegraph lines, it is not so for telephone lines; these to ensure good results, requiring complete metallic circuits in which both wires are parallel and as close as possible to one another.

Electric light circuits should always have a wire return, and, if possible, the out and in wires should pass by different routes.

Telegraph lines of less than half a mile in length, work better when completed metallically than when provided with earth terminals; while telephone lines work well on either, if the contacts are good, and the line is overhead.

For underground lines a loop circuit is preferable, as also where lines are to be frequently connected with double wire trunk lines.

In our large cities, good earth can always be obtained upon water or gas pipes; but a water pipe is always the best, and if accessible should be used. The reason for this preference is that pipe joints are usually made up and luted with red and white lead, which are really very fair insulators, and if a water pipe is used, the liquid itself aids to some extent in conducting the electricity. If both water and gas pipes are accessible, both should be used. If only gas pipes are accessible, the connection should invariably be outside of the meter, as otherwise the removal of the meter which frequently occurs, severs the connection with the earth entirely. If several series of water or gaspipes, or both, are at hand it is advisable to ensure the terminal by connecting the wire from the line with all of them. Wherever a pipe is used for this purpose, it should first be filed, and scraped quite clean and bright. For a short line a good earth may then be made by first winding a long stretch of copper wire of comparatively small size—No. 16 for example, very tightly, smoothly and regularly, round the pipe until some four inches of the said pipe longitudinally are covered with the copper. This can be tightened up by passing the last few convolutions through one another, and while the loose end is yet stretched tight, the whole should be well soldered over, leaving a loose end of about 18 inches long to splice and solder to the wire leading from the main line.

A long line terminal may be treated much in the same way, but instead of one small wire, several should be used, the ends of which may be finally twisted together before splicing to the main ground wire. This wire in long lines ought to be of large size, not less than No. 4 or 6, and before splicing it to the small wires it should itself be twisted eight or ten turns round the pipe. The splice of the small and large wire should then be laid over the convolutions on the pipe lengthways, and the whole again soldered.

Short line terminals, for instance those at the subscriber's end of an exchange telephone line, need not be nearly so heavy, but must certainly be soldered. It is sometimes good practice to employ clamps in such positions. These are adapted to grasp the pipe, and should be provided with a binding screw for attachment of the earth wire. In that case they make a reasonably good connection for a line which is not of great consequence, and have the advantage of being easily attached. They should also have a considerable amount of longitudinal surface and be furnished with a tight clamping screw, or one which has a set nut. If a large and long clamp cannot be obtained, a number of small ones may be substituted, and all ought to have a small movable plate of copper, brass or platinized metal, between the ends of the clamping screws and the pipe, so that not only, the screw ends but a good surface under them, can make the contact with the pipe. The weak point of clamps is their liability to the formation of rust between their inner surface and the pipe; and the tendency of their screws to work loose.

It is often difficult in country places and newly settled districts, to obtain a good connection, as pipes are scarce. In such cases we are compelled to resort to buried plates. Bars or strands of wire rope are by no means so effectual as earth plates. Earth plates ought always to be made of copper or of zinced or tinned iron.

These materials are recommended not on account of any degree of conductivity which they possess, but because by their use, the metallic surface is much longer kept intact,

Digitized by Google

and oxidation retarded. The plates should never be smaller than three feet by four, and they ought to be about one-eighth of an inch thick. Ordinary or unprepared iron is not of much use as it rusts through very quickly. When it is necessary to resort to earth plates, to prepare them in a first class manner, we take two large insulated copper wires (No. 6 for instance) and attach them to the plate by the following mode:—Holes are made across the plate, in two lines, and the two wires are threaded through them—about four holes for each wire will do—the wires are then soldered to the plate at every hole. It should be needless to say that the portion of the wires to be threaded through the holes, must first be stripped of its covering. In setting the plate, the hole should be dug until damp earth is reached, and the plate must be set on edge, so deep that its upper edge does not come above the level of dampness.

All strain is taken from the wires, and above the surface of the ground they may be soldered together, and then spliced or jointed to a single iron or copper wire leading to the instruments and line. The idea of insulating the ground wire has been often ridiculed, yet after careful reflection I am inclined to believe that it is by no means such a subject for mirth as it has been thought. On the contrary, I believe that all points of a terminal earth wire, from the instruments to the ground line, or the pipe, as the case may be, should be well insulated, so that no electrolytic action can arise. When the earth wire is to serve as the terminal of many wires, it should be as large as can be conveniently handled.

Telephone exchanges of many wires can readily be operated without any main terminal earth wire, as each wire finds earth by way of all the others. Some offices are so worked. I have found in practice that it is scarcely an advisable arrangement, since it is quite conceivable that on many occasions, half of the lines may be in use simultaneously, in which case the joint resistance of the compound terminal is much diminished; I prefer therefore even in such cases, to provide an earth terminal of the highest character.

If it is suspected that the resistance of an earth terminal wire is too high, it should be measured, just the same as any other conductor. No earth wire and plate should measure more than ten ohms at the very outside.

Whenever earth plates are employed they should be of the same metal, as otherwise a permanent transfer of electricity takes place from one to the other through the line, for the two dissimilar metals being united by a conductor the necessary conditions for a current are present.

NOISE FROM MECHANICAL VIBRATIONS.

The noise caused by stretched wires when set in vibration is sometimes very loud, and very annoying.. This is one of the most serious objections to housetop lines, and also one which is most frequently urged by occupants of buildings to which the wires are attached. It is generally caused by the wind which exercises some influence on the wires even when its movement is not perceptible to the observer. It is peculiarly emphasized, when a great number of wires pass over and are attached to a building. The building itself, as might be expected acts as a sounding board, and if the wire is strained too tightly the vibration conducted down the frame of the building becomes an insufferable nuisance. Although, as noted above, it is usually to be attributed to the wind it is quite obvious, that such is not the only cause, since the vibration is sometimes at its height when the atmosphere is perfectly still. Every one has noticed the strong clear musical note which proceeds from a pole line, on still frosty mornings. The wires are then by reason of their contraction in response to the low temperature, like the strings of a musical instrument, and are in a condition to vibrate sympathetically with any mechanical vibration which may be occurring in their vicinity. Pole line vibration troubles nobody, and may be left unremedied unless it happens to be very loud indeed. With housetop lines the case is different, the noise must be either removed altogether, or materially tranquilized.

To accomplish this the wires must be *damped*, so as to remove their resonance. Various expedients may be adopted to accomplish this, the best way, however, is to insert a piece of strong chain in the line-wire, connecting the wire firmly to it at both ends, and also bridging the chain with a smaller wire attached to the line-wire at both ends of the chain, and soldered to maintain continuity.

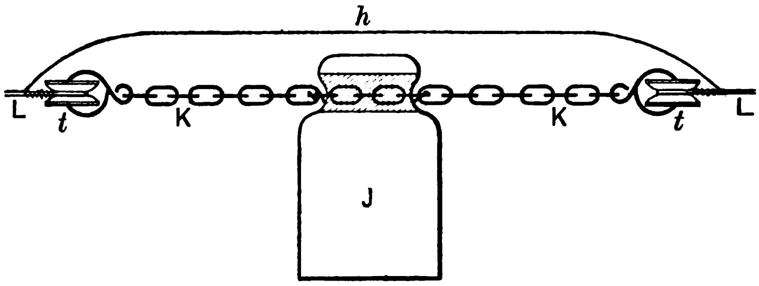

FIGURE 23.

Figure 23 shows how this may be done; the chain is bound to the insulator, which is first wrapped with soft sheet india rubber. In England the insulators are for this purpose sometimes wrapped with vulcanized rubber, or the wire itself is first, at the point of support, enclosed in a soft rubber tube and then wrapped with about a pound of lead wire. I have with telephone wire frequently adopted with success the following expedient:—Two pieces of stout india-rubber tubing like that employed to cover the rollers of an ordinary wringing machine, are cut about two inches long, and one is fastened at each end of a piece of line-wire four or five feet long by passing the wire through it, and twisting it back on itself. The piece of wire is then fastened by its middle to the insulator in the usual way by a tie wire. The main line is then cut, and its divided ends are fastened to the respective sections of hose by passing it round the outside; to preserve the continuity of the line, the small wire is fastened to the main wire, at a point beyond the two ends of the inserted piece, as described with respect to the chain remedy.

(*To be continued.*)

THE CENTRAL ELECTRIC LIGHTING STATION OF MILAN.[1]

BY G. COLOMBO.

WE propose to offer our readers, after 18 months of regular operation, a description of the Milan central station, together with its plant, its system of wires, the results hitherto achieved, and those that may be hoped for in the future.

The construction of this central station was decided on towards the latter end of 1882, by a committee selected to introduce the Edison system in Italy, who formed later the existing company, having a capital of $600,000, bearing the name of the *Società generale italiana di elettricità Sistema Edison*, with headquarters at Milan.

The company, having purchased a building situated in the street Santa Radegonda, formerly used as a theatre, began to demolish the theatre and to construct the new station in the month of October, 1882. The work was pushed so rapidly that the station with the first four machines was ready for work in June, 1883, the underground wires having been laid throughout the principal part of the territory to be covered, during the winter. Toward the end of June, 1883, the station began to work regularly every night until 1 o'clock A. M., with an average of 1,100 lamps. In August, 1883, the lighting of the famous *theatre de la Scala* was undertaken, two machines being

1. *La Lumière Electrique.*

Digitized by Google

added to the existing four, for that purpose; and in November, 1883, continuous service, by day and night, was begun; until by the end of December, 1884, the number of lamps had reached 5,500, equivalent to 4,700 lamps of the normal standard of 16 c. p.

We will divide our description of the Milanese installation, for convenience sake, into the following sections:

1. The central station of Ste. Radegonde; 2. The system of conductors; 3. The principal installations; 4. The general working of the system.

I.

THE CENTRAL STATION OF STE. RADEGONDE.

This is a rectangular two-story and basement building of 147 x 42 feet, situated between the two parallel streets, *Agnello* and *Santa Radegonda.* The basement contains the machines, the next floor the boilers, and the top floor the store room and laboratory. This is a different arrangement to that usually adopted, which is to place the boilers in the basement, and was dictated by considerations of stability, in consequence of the great speed of the machines.

The machine room.—This occupies the whole ground floor, and contains at present six machines, with vacant spaces and foundations for four more, making a total of 10 for the station when it shall be worked to its fullest capacity.

The machines now in use are of the type known as the "Edison c," of which the following are the data:

Maximum current at 110 volts	900 ampères
Electromotive force, at the electrodes	110 to 120 volts
Resistance of armature	0.0039 ohms
Resistance of field magnets	2.28 ohms
Diameter of armature (8 ft. 2 in.)	2 m. 737
Length of armature (5 ft. 2 in.)	1 m. 630
Number of field magnets	12

Each of these machines has its own independent steam engine, of which the shaft is the prolongation of the axis of the armature. The normal speed of the armature, therefore, of the engine shaft is 350 revolutions per minute. Of the engines, two are of the Porter-Allen type, and the other four of the Armington-Sims pattern. Each of these machines can develop, at a maximum pressure of eight atmospheres, a maximum force of 130 to 150 h. p., corresponding to the demand, of 1,200 lamps of 16 c. p. per dynamo. A small separate steam engine actuates a ventilator for the aëration of the dynamo armatures, and a steam pump sends a current of cold water through the interior of the frames and foundations. These means of refrigeration are only needed when the machines are developing their maximum of work.

All the dynamos are coupled in quantity to two principal conductors of 1,700 square millimetres (2.6 sq. in.) section, and connected by means of the necessary switches and flexible copper conductors to the regulators and to the indoor test circuit, and to the two exterior feeding conductors, which enter the building at the opposite corners of this room. A current regulator is provided for each machine. Each regulator is formed of 50 bobbins, coupled so as to interpose in the field circuit of each dynamo a resistance varying from $\frac{1}{16}$ ohm to 7¼ ohms in all. The regulation is accomplished by hand, either for each dynamo singly, or for all at once, by means of a common shaft which rotates all of the contact arms. These are movable over the six discs of the regulators, each having 57 connectors representing 57 degrees of strength of current. Two indicators of electromotive force with electric bells, and two dial voltmeters are used by the persons who have charge of the regulation of the current. These instruments are regulated by a standard voltmeter, graduated by means of a standard Daniell cell and by a Thomson reflecting galvanometer. By this means the current is promptly regulated without alteration in the quantity of light furnished, even when the greatest alterations are made—such, for instance, as the sudden lighting or extinction of hundreds of lights at a time, for scenic effect in the *theatre de la Scala.* A local circuit, called the test circuit, is arranged so as to be traversed at the will of the attendant by the current from each of the dynamos. On this circuit are connected 1,000 lamps, or as many as should be operated by one machine at its maximum rate of work. These 1,000 lamps can be lit by groups of 50 at a time, by the aid of a switch. At the junction of the two principal conductors with the feeding conductors of the system are interposed feed-regulators, which will be explained later in our description of the system of conductors; their function is to equalize the electromotive force, and consequently the intensity of the light, at all points. In this room are also placed the ammeters used to indicate the quantity of current flowing through the system of conductors, and therefore the number of lamps lighted in the territory supplied by the station. These ammeters are simple needles, deflected by the current which passes through the principal conductors, placed beneath them, and can indicate up to 2,000 ampères with a trifling error; they are verified from time to time by standard lamps. Although it would be easy to furnish these ammeters with automatic registering devices, which may be done later, at present it is considered sufficient to read the indications once every quarter hour, as much for regulating the machines then working as for registering the course and amount of the daily work performed. Other apparatus, unnecessary to describe here, serves for diverse observations, such as the variations in the electromotive force at the ends of the feeding conductors of the system; indicators of leakage to earth on either pole of the system of conductors; measures of the corresponding electromotive force, etc.

Boiler room.—The boilers are installed in the first story, and at present are five in number, of which one is isolated and the other four connected in groups or batteries of two boilers each. They are of the Babcock & Wilcox manufacture, perfected in many details by Root. The choice of boilers was determined by the local conditions, which demanded boilers of a pattern at once light, small in comparison with the considerable force required, and inexplosive. Each boiler is composed of a group of inclined tubes, connected at the two extremities to horizontal reservoirs of steel plates, from whence the steam is drawn. The interior extremity of the tubes is in communication with a drum, from whence the smoke passes to the chimney. The principal data of each of these five boilers follow:

Number of tubes	96
Number of collecting reservoirs	2
Length of tubes	15 feet
Length of reservoirs	15 "
Surface of grate	12 sq. "
Heating surface, nearly	510 " "
Estimated h. p.	160
Total weight	42,944 lbs.
Surface occupied	60 sq. feet

Space has been left unoccupied for four more boilers, in case the wants of the service shall render them necessary. The boilers are fed by five Koertig injectors, two of which pump the water from the bottom of a well and empty it into reservoirs situated on the lower floor. There are also two direct-action steam pumps, of which one is ordinarily used for the refrigeration of the machines; but the piping is so arranged that either of these pumps, or both together, may be used for feeding the boilers. The steam pipes are so arranged that either machine can be detached from the others in case of accident, or for repairs.

The smoke from the boiler furnaces is carried to a chimney of 6 feet constant interior diameter, and is 156 feet in height from the street pavement.

Other apparatus is used for the hoisting and distribution of the coal. The coal burned is the best Cardiff, which produces very little smoke when the furnaces are

Digitized by Google

charged, and practically none during combustion. No smoke-consuming devices are used.

Organization of the central office staff.—The direction of the service is confided to an electrician-in-chief, who has under his immediate orders: One or two engineers, according to the season, charged with the oversight of the work; one chief mechanician; one foreman electrician; one foreman mechanician; one foreman of firemen; and the working electricians (for the commutators), steam engineers and firemen. The staff is divided into gangs for day and night service.

During the summer season the number of lamps used in the district during the late hours of the night and during the day is only from 100 to 200; during the winter this number increases, and there are some days on which the lamps are in use by hundreds from daybreak, and in some places of public resort remain in use all night. During the hours when the lamps in use are only some hundreds, a small 400-light dynamo is used. As soon as the ammeters indicate that the number of lamps in use approaches 400, one of the large dynamos is started and the small one stopped. A second C dynamo is added when more than 900 lamps are indicated; for although the C dynamos will feed 1,000 lamps, and even more (with the maximum electromotive force of 116 volts), it is preferred not to charge them in actual service with more than 900 or 950. The same proceeding is repeated in proportion as the number of lamps used in the district increases, until the full capacity of four dynamos is reached, and this has not been exceeded up to the present time. The remaining two machines are kept in reserve, one of them being run at a reduced speed on open circuit, ready for use in a few moments if the occasion arises. Experience has shown that the introduction of a new dynamo, or the substitution of one for another, can be made in a few seconds, and in such a manner that an accident to a machine, such as the breaking or the heating of a part, has no injurious effect on the regularity of the service.

The increase in the number of lamps takes place very rapidly from twilight to 7 or 8 o'clock in the evening. The process above described is reversed in removing dynamos one after another from the circuit, when at a later hour the number of lamps begin to decrease. Ordinarily, one hour after the closing of the theatres the small dynamo is put in use.

The normal electromotive force of the station is shown by the indicators previously mentioned, whilst that at the end of the feeding conductors is regulated by means of the feed-regulators according to the indications of the ammeters. Thus the director of the station has completely under his hand the working of the lighting at all points of the system.

All of the statistics relating to the work of the station, as well as the number of lamp-hours, the consumption of coal and oil, etc., are registered daily and tabulated monthly for the information of the engineer-in-chief and for the administration.

II.

SYSTEM OF CONDUCTORS.

The central station of Ste. Radegonde, which at present is eccentrically situated in respect to the district served by its conductors, will on account of recent developments of the system of conductors, soon be in a central position, with radii of 1,500 to 1,600 feet in all directions.

The conductors are divided into two classes, called respectively *conducteurs d'alimentation* (feeders), and *conducteurs distribution* (mains), the distinctive uses of each being explained hereafter. Each line comprises two conductors, one going and the other returning, that is to say, each line is a tube containing two copper conducting bars separated by an insulating composition, according to the well-known Edison system, which has been previously described in these columns (see page 95).

The organization and manner of calculating the details of such a system are quite different from those required for any other conduits, as for water, air or gas. In such cases we start with a certain initial pressure (in the reservoirs, or in the gasometer), and the conduit is so designed as to lose a certain determined fraction of the initial pressure at the most distant points of the system. We have then at different points of the system at pressure, which is less and less in proportion as the distance from the origin of the conduit. The maximum loss of pressure may represent a considerable fraction of the initial pressure, since we can always proportion the delivery of the water, or gas, by appropriate orifices, whatever may be the pressure, or rate of flow, and thus compensate for diminished pressure.

For an electric lighting conduit, the problem is entirely different. Admitting as a general principle, that it is desirable to employ for the service throughout the whole of a system lamps of one standard form, which is equivalent to demanding the same electromotive force to develop their normal luminous intensity, it is evident that the permissible falls of potential between the two conductors, at any two points of the system must not vary much between themselves, without having lamps which would give a luminous intensity varying too much according to their positions relatively to the source of current.

Then, recalling the fact that for the standard Edison 16 c.p. lamp, a difference of one volt in the electromotive force, is equivalent, at the limits of the luminous intensity, to nearly one candle, one can easily comprehend that the greatest available difference in electromotive force at any two points of the system cannot without inconvenience exceed one and a half or two per cent. It is then necessary to design the system so that this condition may always be fulfilled; and this consideration forcibly excludes the application of the system in use for the distribution of water or gas. Strictly speaking, one could make up for a great variation in the available electromotive force by using lamps giving the same luminous intensity with different electromotive forces (that is to say, having different resistances), but that would entail complications in the service, which are entirely inadmissible.

To satisfy the condition stated it is necessary to divide the system of conductors into two parts: first, a system of conductors called mains, forming a circuit entirely closed and isolated from the central station; and second, a system of conductors called feeders, which, starting from the central station, carry the current to conveniently chosen points on the mains. This might be compared to a distribution of water by a system of intercommunicating canals, into which the water would be carried by feeding trenches proceeding from the source of supply, so as to establish an equal level at all points of the system.

The conductors forming the closed system of mains are those which run along the streets and serve directly for the distribution of the current to the houses of consumers.

They are inter-connected by joint-boxes containing fusible lead safety-plugs, calculated so as to interrupt the circuit whenever from any cause the delivery becomes abnormal and threatens to heat the conductors above the fixed limit.

The feeding conductors all start from the central station, and are all connected with the mains in joint-boxes of the same sort as those used for the mains. These joint-boxes have openings flush with the pavement, for the purpose of examining the joints and of making galvanometer tests.

The designing of a system of this sort can all be done with a battery and galvanometer, in the laboratory. An artificial system, on a reduced scale, is constructed to represent the actual system; the current is passed from the battery by feeding conductors branching to different points and always of the same resistance; then by experiment it is determined which are the most convenient points at which

Digitized by Google

to make the junctions between the feeders and the mains, so that the difference of potential between any two points on the mains shall not exceed the fixed limit. Only, as it is impossible that a system thus planned shall not be subjected to subsequent changes by reason of the addition of new consumers, it becomes necessary to also arrange for the growth of the mains; this requires a somewhat laborious calculation to determine whether one or more feeders shall be supplied, or whether the points of junction between the feeders and the mains shall be displaced.

It was in this fashion that the existing system, planned first in the laboratory for about 3,000 lamps and extending only to *la Scala* theatre, about 1,380 ft. from the central station, has since been enlarged by the addition of two feeders, the displacement of several junction boxes, and the lengthening of all of the mains, so as to suffice for the 5,500 lamps now served, with the possibility of serving 7,000 without any further alteration, at a maximum distance, by the conductors of 1,890 feet, and 1,440 feet in a straight line.

The mains generally run on both sides of each street in the district served by this station, and are buried at a depth varying from 20 to 30 inches beneath the pavement. The tubes containing the mains are of No. 4 size, having two bars of copper of 930 square millimetres (1.44 sq. in.) each and 6 metres (19½ feet) long. The joints are made on the well-known system, by arcs of copper in cast-iron boxes, filled with the insulating composition. Twelve joint-boxes are used for the mains.

The loops to the houses of consumers are made by boxes of a special shape, from which the conductors are carried either in smaller tubes (Nos. 5, 6 or 7), or by lead-covered cables, and are then subdivided into distributing wires leading to the different places to be lighted.

The feeders are placed at the same depth, branching to the selected points on the mains by the shortest route and connected to the mains by six-joint boxes similar to those used on the mains. The feeders are large tubes of Nos. 1½ and 2 size, containing bars of 589 and 443 square millimetres (0.91 to 0.68 sq. in.) section. The shortest is 118 metres (383 feet) long, and the longest 504 metres (1,638 feet). Their resistance is from 0.0101 to 0.0393 ohm. The insulation resistance of all of the underground conductors connected together is 192,000 ohms.

The maximum loss for which the conductors have been calculated is 12 volts, when all of the lamps served by the station are in use. Adding the loss in the installations in the consumers' premises, calculated to be from 2 to 2½ volts for all of the installations, there is a maximum loss of electromotive force between the dynamos and the lamps of 14 to 14½ volts.

With the great variations in the consumption of the current caused by the addition of new consumers, the opening and closing of theatres, etc., it would not be possible to preserve a constant electromotive force, even within the limits indicated, at different points of the system, without the use of the feed-regulators at the ends of the feeders in the central station. By the aid of these the greatest variation in the available electromotive force at any two points of the system never exceeds 2 volts, or less than two per cent. of the standard electromotive force, adopted from the start which is 102 volts. Thus all consumers of Milan are served by lamps of 101 to 103 volts, limits which are never passed.

The theatre of *la Scala* being the most important consumer of the system has been the object of special precautions in designing the arrangements.

Notwithstanding the doubts expressed by many electricians, including Mr. Edison himself, the theatre has been connected directly with the system, although it uses an equivalent of 2,580 16 c.p. lamps and that exhibitions take place there only during the first three or four months of the year. It has been arranged so that it can be operated by an isolated plant if necessary, but up to the present time it remains connected with the general system.

We give below some data as to the extent of the system.

	Feet.
Length of tubes for feeders and mains	23,075
Average distance from the centre of gravity of the lighting from the station, measured on the conductors	1,430
Distance from the station to the centre of the principal group of lamps (around the theatre of La Scala) measured on the conductors	1,625
Distance from the station to the most distant lamp (Banca generale) measured on the conductors	2,047
Distance from the station to the most distant lamp in a straight line (Hotel Continental and Cercle des Artists) or maximum radius	1,560

III.

THE PRINCIPAL INSTALLATIONS OF THE SYSTEM.

On January 1st, the system comprised 5,530 lamps, equivalent to 4,745 of the standard 16 c.p. lamps, thus distributed.

	Lamps.
Theatre de la Scala	2,890
Theatre Manzoni	391
Hotel Continental	476
Cercles (clubs)	335
Cafés and Restaurants	725
Banks	103
Stores and dwellings	610
Total	5,530

Of these the most important is that of *la Scala* theatre. This is the largest opera house in the world, so far as the dimensions of the stage and auditorium are concerned, although the space allotted to the necessary portions not used by the public are somewhat restricted, owing to lack of ground. The stage is 147 feet deep by 121 feet wide. The auditorium is 81 by 71 feet, and 65 feet in height. There are 194 boxes, distributed in five galleries, not counting the upper gallery. The theatre was first opened on August 3d, 1778.

The municipal authorities insisted that the whole theatre should be lighted by electricity, to the entire exclusion of gas, at a time when the central station had just begun operations, allowing only five months in which to complete the installation. Happily, the installation of the Theatre Manzoni, just then completed, furnished an opportunity for the study of the apparatus for stage lighting which was to be used on a tenfold greater scale at *la Scala*. Yet much special apparatus for the purpose had to be invented to fill the peculiar demands of a stage so vast and where so much luxury is displayed in the mounting of the operas. The gas was entirely displaced and the theatre wholly lighted by incandescent electric lamps in time for the season 1883–84. The following are some of the details of this important installation: The total number of lamps in the theatre and its annexes is 2,890, of 32, 16, 10 and 8 c. p., respectively, equivalent to 2,580 of the normal 16 c. p. standard lamps. The current is furnished to the theatre as to all other consumers, night and day, and during one season the consumption has amounted in round numbers to 900,000 lamp-hours. Not a single accident to, or interruption in the service, has occurred since its inauguration in November, 1883, up to the present time. A second and much smaller installation is that of the Theatre Manzoni —391 lamps—from whence gas is also excluded.

Another installation, that of the Grand Hotel Continental, is, we believe, unique. This hotel is entirely lighted by incandescence, to the absolute exclusion of gas, and even of candles, since every room is furnished with the electric light. Portable lamps with flexible conductors and circuit-closers similar to those used for electric bells, are used. There are 476 lamps here, 32 and 16 c. p. being used for the public halls and saloons, and 10 c. p. for the chambers.

Two or three other installations are now in course of

Digitized by Google

construction, and are rapidly approaching completion. As the gas company in this city has an unexpired monopoly, it is impossible to hope for a much greater extension of the system to streets and squares other than those now covered, although the public much desire it. The electric light has, however, brought about a reduction of 40 per cent. in the price of gas within the district served.

IV.

THE GENERAL WORKING OF THE SYSTEM.

When this enterprise was undertaken, there was only one other like it in the world, at New York, and even there the Pearl street station had only just started to furnish light. It follows, therefore, that its operations were conducted slowly, and often tentatively. Nevertheless, it prospered so well that on December 31st last it had a number of consumers which represented an annual revenue of $40,000.

At the present moment, the capacity of the six machines now installed at Ste. Radegonde is nearly reached. As the principle has been adopted of always keeping one in reserve, even in the times of greatest consumption (the month of February), and calculating the capacity of the c machine at 1,000 16 c. p. lamps, the present equipment will only supply 5,000 of 16 candles, or their equivalent in 32, 16, 10 and 8 c. p. lamps. The station can contain, however, and has fixtures ready for, four more machines and all accessories, capable of supplying, omitting the reserve, 9,000 16 c. p. lamps, or about 11,000 of assorted sizes. This number will suffice for the probable extreme wants of the entire district.

The new machines can be added at a less proportionate cost than the six original ones, on account of the preparation already made to receive them. The cost will be simply the purchase price of the machines and conductors, and cost of laying them. In regard to the conductors, any additions to the number of consumers will result in allowing a more favorable arrangement of the junctions between the feeders and the mains, so that the cost of these will be, per lamp, about 40 francs ($8.00), as against 56 francs ($12.00) for the original outlay per lamp. It may therefore be concluded that the first year of working the Ste. Radegonde station does not represent exactly the results that may be expected in 1885. So, if the first year of working has not only left the capital intact, but has produced a margin for renewal of the plant, it may be expected that the succeeding years will produce dividends. Not only will the diminution in the first cost of installation tend to this result, but also the greater economies which will be realized in the maintenance. In launching a new enterprise where it is imperative to succeed at any cost, notwithstanding obstacles, details receive little attention; but when the business is once well under way, the staff have leisure to economize in the working. One example suffices to prove this: The consumption of coal, which was at .50 kilos (1.1 lbs.) per 16 c. p. lamp per hour, has been reduced to .35 kilos (.77 lbs.) at present, with a prospect of a still greater economy in this particular. All of the other factors in the cost of working have been diminished in like proportion.

When the enterprise was started it was judged convenient to adopt a mixed tariff, depending on the nature of the consumption, viz.: a fixed tariff of so much per lamp per year for places like theatres, cafés, clubs, etc., where the average consumption per year varied little; and a tariff depending on the actual consumption, measured by the Edison metre, for private houses, stores, banks, offices, etc.

As to the tariff itself, the system adopted from the start was the most rational and the most convenient that could be adopted for an electric lighting enterprise, especially at its inception. Each lamp installed with a consumer represented a capital permanently invested for real estate, building, machinery and conductors. Even supposing that lamp to be used only one hour per year, the installation must provide for illuminating that lamp, since it might happen that all of the lamps in the system should be in use at the same time. This is especially true in Milan, because the lamps being chiefly in public places, it really happens that in winter, at a certain hour of the night, the greater portion of the lamps are in use. Each lamp installed ought, then, to pay the interest and the cost of renewal of its share of the capital invested, whether used during the whole year or not at all. This constitutes, in consequence, an *annual constant* that each lamp must pay, independent of its consumption.

Then there remains to be fixed the tariff of consumption, representing the cost of coal, labor, maintenance and spare materials. As this cost is nearly proportional to the time the lamp is used, this tariff is so much per hour per lamp, or rather, so much per hour and per ampère consumed by the lamp.

If the contract is by metre, the consumption is paid by the readings of the meter, which registers the quantity of current or the ampères consumed. If the contract is per lamp, the total hours per year are calculated; only, to check a consumption of light greater than that agreed on or foreseen, the consumer must pay, besides, for the renewal of the lamps. Up to the present time the latter form of contract prevails; but for stores and dwellings the tariff by metre is preferred, and will be applied on a more extended scale hereafter.

The following is the tariff adopted from the commencement, and having proved convenient by experience, is maintained integrally at present; it is based on the normal lamp of 16 c. p.:

	Francs.	Dollars.
Annual constant for the 16 c. p. lamp..............	35.00	(7.)

Tariff of consumption:

Per ampère—hour..................................	0.0533	(.01)
Per lamp, normal—hour...........................	0.04	(.008)

For lamps of 100, 32, 10 and 8 c. p., the constant and tariff of consumption are varied proportionately to the quantity of current which they expend.

It is evident that this tariff favors the largest consumers; not those who have the largest number of lamps, but those whose lamps are used during the greatest number of hours. Thus, for example, a consumer whose lamps burn during 3,500 hours per year (as in the case of street lighting), would pay annually for a normal lamp of 16 c. p. (equivalent to at least 180 litres of gas), a sum of 175 francs ($35), which amounts, per hour, to:

	Centimes.	Cents.
16 c. p. electric lamp..............................	5.0	1
Corresponding price per cubic metre of gas......	27.8	5.5

Which demonstrates the possibility and even the convenience of applying the electric light to public lighting.

Cafés, restaurants, clubs, etc., have an average consumption of 2,700 to 2,800 hours, which amounts to a tariff per hour of:

	Centimes.	Cents.
16 c. p. electric lamp..............................	5.25	1.5
Corresponding price per cubic metre of gas.......	29.2	5.8

Stores closing at from 9:30 to 10 o'clock P. M., and having an average consumption of 1,400 hours, would pay per hour:

	Centimes.	Cents.
16 c. p. electric lamp..............................	6.5	1.3
Corresponding price per cubic metre of gas.......	36.1	7.2

The price of gas is that of the monopoly accorded to the gas company of Milan, without counting 2 centimes ($.004) municipal tax.

Lastly, for dwellings and offices closed in the evening, counting the cost of the light on a basis of 700 hours per year, the tariff per hour would be:

	Centimes.	Cents.
16 c. p. electric light..............................	9.0	1.8
Corresponding price per cubic metre of gas.......	50.0	10.0

Digitized by Google

The electric light is in this case dearer than gas, even at the price assured by monopoly, except in small towns, where gas costs, in Italy, 45 centimes (9c.), and even 50 centimes (10c.) per cubic metre. This is also the case with theatres having a small number of representations per year. In Italy, for example, all the large opera houses have a season of 40 to 60 representations.

These figures will suffice to give an idea of the conditions in which an incandescent electric lighting enterprise can be established and compete with gas. They certainly do not represent the last word that can be said of electric lighting. In the future we are sure that reductions will be made which will still further extend this grand application of electricity, which is still in its infancy, since there are but two instances of its exploitation on a large and important scale, viz., in New York and Milan.

As the cost of canalization increases rapidly as the distance between the central station and the furthest outlying lamp increases, it is most economical to establish stations in thickly settled districts, so that this distance shall not much exceed 300 metres (975 feet). If this light is to be adopted generally, to the exclusion of gas, a cheaper system of canalization must be devised. There is more than one way in which a practical solution of this problem may be sought; and although this solution may be reserved for the future, there is already one point gained in a fact whose importance surpasses that of all other accessory questions. This fact is the complete and practical success of public lighting by the incandescent lamp, together with the admirable system of distribution devised by Mr. Edison; a success which is hereafter assured by an experience of more than two years in New York, and of nearly two years in Milan.

SANITARY SUPERIORITY OF THE ELECTRIC LIGHT[1]

BY P. H. VAN DER WEYDE, M. D.,

President of the N. Y. Electrical Society.

The paper which I will read to you to-night, was prepared two years ago, in response to an invitation to furnish an article upon a sanitary subject for a journal devoted to that branch of science. This request arose from the publication of my report upon the defective sanitary condition of the court-house in Brooklyn which appeared in the *Eagle* of that city. Illumination by electricity being then one of the most important subjects attracting public attention, I decided to take it as my theme for the desired article, but upon its presentation I was informed that as it was a strong plea in favor of electric illumination, it could not be made use of for the journal in question, which was devoted to the interests of gas and gas-fitters.

I laid the article aside, but as the subject has received but little attention, I concluded to give it further publicity through a paper devoted to electricity, and to bring it, with some additions, before the New York Electrical Society.

Apart from the theoretical consideration which I will refer to further on, I will first call attention to the result of experience in the use of illuminating gas in libraries. It has been found that in the course of a few years, the books, and more especially the leather bindings become ruined, when the products of gas combustion daily pervade the air of the rooms. For this reason the trustees of the Astor library decided to dispense with artificial illumination, and open the rooms only during the day. The same rule has been adopted by other libraries, which, like the Astor, are especially devoted to the accumulation of books so rare and expensive, that comparatively few individuals can afford to purchase them, and which would therefore be inaccessible to those for whom they are the most useful, namely, the workers in science, art, and literature, who too frequently have neither time, opportunity, nor disposition to acquire wealth.

There is a very meritorious corporation in New York, the Historical Society, the rooms of which are often open during the evening, and its library, museum and picture gallery profusely illuminated with gas. Besides the injustice done to the artists by the yellow gas illumination of their paintings, and the gradually increasing injury done to them as well as the books in the library, I feel impelled to direct special attention to the famous Egyptian antiquities in possession of the society. They must suffer injury and will no doubt eventually be ruined. Forty years in our moist and variable climate, and placed in rooms frequently illuminated with gas will be more detrimental than the 40 centuries they were entombed in the pyramids, in the dry climate of Egypt. The rolls of papyrus covered with hieroglyphics, which have not yet been translated, will surely go to ruin, and before it is too late, they should be reproduced by a photographic process. This may be done on the spot by the electric light, without difficulty. Copies of such a publication sent to prominent antiquarians and the cognate institutions of Europe, would surely contribute largely to our knowledge of that ancient cradle of civilization from which Moses, that great reformer of the Semitic race, obtained his knowledge, and let us not forget that our modern civilization and religion is nothing but a continuation of the Jewish civilization originally derived from Egypt.

A few years ago I proposed to that society the publication of photo-engraved copies of these manuscripts, and if it is not done soon, I hope that the society will at least soon become convinced of the necessity of substituting the electric light for gas in the building, in order to arrest further decay of antiquities which cannot be replaced.

The theoretical considerations relating to the difference between electric and other systems of illumination, from a sanitary point of view consist chiefly in the fact that electric illumination does not involve the combustion of any material, consequently it does not deprive the atmosphere of its oxygen, while other methods involve the feeding of the flame by combustion and consequent absorption of atmospheric oxygen, necessarily resulting in the production of various gases, the principal of which is carbonic acid, carbon being the main element of the substances used for feeding ordinary illuminating flames.

In electric illumination combustion is not the source of light; it is true that in the electric arc, there is a slight consumption of the carbon points, but this is so very small as to be of no practical account, while with the use of the incandescent light, enclosed in an air-tight glass globe, there is no consumption of material whatsoever, except, when by some accident to the glass globe, air acquires access, in which case the lamp commences to burn in reality, and its life is extinguished at once. For this reason I object to the common expression that the incandescent lamps are "burning," or that the "burners are lit," or that certain "lamps have burned for say 50 nights." I refer to any authority for the definition of the word "burn," Webster says, "to consume with fire, to reduce to ashes; surgically, to cauterize; chemically, to combine with oxygen," etc.

Ordinary combustion therefore robs the air of oxygen continually, and this is a most important objection against illumination of that character. It is well known that the life of man is sustained by the continual absorption of oxygen, chiefly by the lungs, but also by the whole skin. The amount thus absorbed is 16 pounds per day, which being diluted with four times its amount of nitrogen, involves the consumption of 80 pounds of pure air every 24 hours, or more than 3 pounds per hour. Considering the small weight of air (which for the same bulk is some 1,000 times lighter than the human body), this is a large quantity, being some 300 gallons of pure air per hour, or five gallons every minute, of which a little over three gallons is respired by the lungs, and the balance by the skin, which takes a

1. Read before the New York Electrical Society, June 10, 1885.

very active part in the elimination of effete gases from the system. The estimate here given is based on carefully conducted experiments, and is a striking proof of the importance of living in a pure atmosphere. It explains why a change of residence, even if only from one house to another, may involve important consequences in regard to the health of the inmates.

If now the continual consumption of pure oxygen is so important to the maintenance of health and life, it is evident that anything which tends to diminish the amount of oxygen present in the air, and to deteriorate the atmosphere in which we live and breathe, should be avoided.

We must next consider that experiments have also proved that every candle flame consumes as much oxygen as a man, and a lamp or gas flame from two to three times as much, and that they discharge the products of their combustion into the atmosphere. These products are, as stated above, chiefly carbonic acid, the same as exhaled by man, while, when lamps are imperfectly burning, the very injurious carbonous oxide may be produced, and other obnoxious gases, as every one knows who has ever experienced the odor of badly managed kerosene lamps. Common gas is often not free from sulphur, or other objectionable ingredients, throwing sulphurous and other vapors into the atmosphere.

Considering all this, it is evident that our common methods of illumination, at the expense of the pure atmospheric oxygen, which we need for breathing purposes, is highly injudicious; and it is no wonder that when they have been applied in crowded localities, where inferior provisions are made for ventilation, injurious, if not fatal results have been experienced.

The electric light, on the contrary, is produced by an agency outside of the localities which it illuminates. It is the combustion of the coal which heats the boilers, the steam generated drives the engine, which moves the dynamo-electric machine, and this generates the electric current, which ultimately produces the light. Combustion is also here the source of the light, but it takes place in a furnace, *and the products of this combustion are not thrown into the locality to be illuminated, but at a great distance through a chimney into the free air, and the chain of different activities involved in the operation has for its final result the total separation of this combustion with its flame, heat and smoke, from the light-giving apparatus, while in the ordinary methods of lighting they are all united in the room to be lit.*

The electric light possesses two additional advantages; it does not heat the air of the locality it illuminates, and in its nature approximates sunlight, more nearly than any other source of illumination known, which two points are also of sanitary importance. Keeping the atmosphere cool in crowded localities, rather than adding to it by numerous flames, is surely beneficial, while when properly used and screened, the cool, pure and white electric light must necessarily be better for the eyes and for the whole system, than the yellow light produced by flames, while its beneficial effects in the growth of plants have been the subject of experiments, which promise favorable results when properly applied.

Its similarity to sun or daylight, which is decidedly the most beneficial of all illuminations, is also proved by the success of making photographic pictures at night, in London, Paris and New York, by means of electric light, which pictures are taken in as short a time as daylight pictures, while in regard to artistic effect of light and shadows they leave nothing to be desired if the illumination of the sitter is only properly managed.

This consideration of the great amount of heat produced in common gas flames, and its almost total absence in electric light, is also important from an economical standpoint. In the combustion of gas, more than 95 per cent. of the latent energy is transformed into heat, and less than five per cent. into luminous rays, while in the case of the electric light it is the reverse, more than 95 per cent. of the electric energy being transformed into light, and less than five per cent. into heat.

In the case of gas, the heat is diffused by air currents through the whole locality, if no extraordinary measures have been taken to remove the products of combustion through expressly constructed channels, while in the case of electric light the much smaller quantity of heat is confined to a single spot, where, by its concentration, the temperature is much higher than that of any flame, but the confinement in the limited space prevents the diffusion of the heat, while that of the intense light is radiated freely.

The readiness with which we adopt improvements, such as electrical illumination for practical purposes, and the customary tardiness in this regard in Europe is illustrated by the two famous tunnels, the attempted tunnel under the Hudson River, New York, and the St. Gothard tunnel in Switzerland. In the first, electric lights were used from the beginning, while in the St. Gothard tunnel oil lamps were used, and in such numbers, that, according to the reports of visitors, the smoke was suffocating, and the heat 106° Fah. This is not to be wondered at, when we are informed that the number of men employed was 2,400, most of whom had a lamp each, while the daily consumption of oil was 150 gallons. More than 200 men have been killed by accidents, a greater number have been injured, while a still greater number succumbed or were obliged to abandon the work, being compelled to do so by reason of the stifling heat and smoke-laden atmosphere. We consider it criminal neglect not to use electrical illumination for an engineering work of this kind.

In regard to the objection sometimes made, that the glare of the electric light is unpleasant to the eyes when looked upon, we may answer that the solar brightness may be objected to, upon equal grounds. But nobody desires to stare at the sun; experience teaches us not to do so, and such will also be the case with the electric light. Then this objection will disappear, in fact, it has already passed away.

No doubt many of you have read with pleasure, if not with pride, the acknowledgement by Mr. Preece, the head of the British telegraph system, of the superiority of the electric illumination of our cities and towns over those of England. In an article, republished in most of our electrical papers, he refers to the gloominess he experienced upon his return to the streets of London illuminated only with gas, compared with the brightness of the principal thoroughfares of New York, illuminated as they are with brilliant arc lamps. This acknowledgement from a gentleman of his reputation, gratified me, especially as a little while before I had a discussion upon this topic with a member of the British Association whom I met in Montreal, and who insisted that New York was not to be compared with London, that he had been unable to find incandescent lamps in New York, and that the arc lamps he had seen were miserable. He was a specimen of a prejudiced man, who had no desire to see anything praiseworthy among us.

THE TELEMETER AND ELECTRIC LIGHT.

The incandescent light has been applied to the internal illumination of the telemeter by a committee of the German army. The lamp is placed in a little lateral tube or recess normal to the main lunette of the telemeter, and between the eye and cross wires. The lamp is lighted by two bichromate of potash cells. The light of the lamp passes through a small hole in the wall of the lunette, and illuminates the cross wires. This illuminating of the wires is found to double the distance that the telemeter will measure, thus rendering it still more serviceable as a means of coast defense.

PROTECTION AGAINST LIGHTNING.[1]

BY ALEX. MC ADIE.

In his *Experimental Researches*, paragraphs 1173 *et seq.*, Faraday describes the miniature house he had built to test the question of protection from electrical discharges. It was a hollow cube some 12 feet high, wound around completely on the outside with wire. "I went into the cube," he says, "and lived in it, but though I used lighted candles, electrometers, and all other tests of electrical states, I could not find the least influence upon them, or indication of anything particular, given by them, though all the time the outside of the cube was powerfully charged and large sparks and brushes were starting off, from every point of its outer surface." Faraday's experiment is further exemplified in all modern forms of electrometers. It is necessary, of course, to shield the essential parts of the instrument from external electrical influences, and to do this the enclosing walls are generally tinfoiled, making practically an outer metallic covering. From mathematical considerations, it follows that the potential within a hollow conducting globe is constant. Electrical action external to this globe can have no effect on bodies within it, because their potentials being the same there is no difference of potential, and, consequently, no work can be done. From these considerations it is evident that a metallic covering would afford to objects within, certain protection against lightning. Maxwell, who did for electricity mathematically what Faraday did for it experimentally, in 1876, suggested to the British Association the plan based on the experiment of Faraday's quoted above,—of protecting a building from the effects of lightning by surrounding it with a sort of cage of rods or stout wire. The suggestion has not yet been applied practically to any extent, but nevertheless it remains the only suggestion of any value made in connection with the question of protection against lightning during the past 50 years. The effective lightning protector of the future will certainly be one based on Maxwell's suggestion. The lightning-rod as it now exists is not, as is too frequently supposed, a modification of Faraday's external metallic shield. The theory of the lightning-rod's action is altogether different from that of a metallic covering. The lightning-rod's efficiency depends on the properties of points in dealing with electricity. If an electrified body is brought near a conductor, it induces on that conductor an opposite electrification and is more or less attracted to it. If we fix a point to the conductor it will, under certain conditions, give off the induced electricity to the air, which if it come in contact with the inducing body will neutralize a like amount of the opposite electricity. A thunder-cloud being an electrified body induces on the earth a charge of opposite nature and the lightning-rod affords means for a partial neutralization. As Prof. Tait puts it, "a lightning-rod serves, rather to prevent the occurrence than to ward off the effect of the lightning flash." Experience shows very plainly that lightning-rods are useless against ball discharges of lightning or, in fact, any intense disruptive discharge. The theory of the rod's action requires that this should be so. Ordinarily as the thunder-cloud approaches, a convective discharge or glow occurs at the point of the lightning conductor (always provided that this is in good conducting connection with the ground) an evidence of the escape of electricity of an opposite kind, and a consequent neutralizing of that of the cloud. This silent discharge of course tends to prevent the disruptive discharge in which the danger lies. Under certain conditions lightning-rods may be forced to carry a disruptive discharge, a use for which clearly they are not primarily designed, and in which failure to retain and lead off the current imperils bodies in the vicinity of the rod.

Prof. Le Conte has pointed out (*Nature*, Feb. 24, 1881) that the path of the discharge, whether disruptive or convective, depends upon five variable conditions :—

"1. *Distance* of the thunder-cloud from the point of the conductor.

2. Variable dielectric properties of the intervening air.

3. Size of the cloud.

4. The variable tension of its electrical charge especially under the neutralizing action of the pointed rod.

5. The *velocity* with which the thunder-cloud approaches the point of the conductor, this last consideration being very important and at the same time difficult to formulate."

The rod may be inadequate to overcome the result of a sudden variation in one or more of these conditions, in which case a disruptive discharge of a violence correspondingly to the degree of the variation must ensue. The question then is, whether the lightning conductor affords a more attractive path to this electricity of high tension than other objects in the immediate neighborhood. If the rod does, it is eminently a protector; if it does not, it is a source of danger.

The space protected by a lightning conductor, is not, as is often laid down in treatises on the matter, a circular space whose radius is twice the height of the rod. Such a rule has never been verified experimentally, nor is there any good theoretical reason why it should be so.

As to the actual construction of lightning-rods in this country, a brief inspection of all the patents issued in the United States during the past six years on lightning-rods may be both profitable and interesting. The number of patents awarded is surprisingly small.

	Rods.	Conductors.	Couplings.

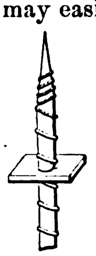
In addition to these there were patented : One machine for making lightning conductors at the place of erection, the inventor of which is a "down-easter"; four devices for protecting oil-tanks, all of which are common connections of the metal of the tank to the ground ; one lightning-rod ornament, one lightning-rod stand, and one tripod stand. The distinction between the rod and the conductor is that the rod is that part of the conductor which is pointed. Among these patents there is no one device especially ingenious or noteworthy. Good couplings are important, for a poor connection between sections of the conductor may easily render the whole worse than useless. The construction of a good coupling, however, is not difficult. Any good metallic binding that will hold fast and is not exposed to rust is sufficient. Several of the couplings patented seem well adapted for their purpose. Among these are couplings consisting of metallic boxes, hollowed out and secured to the sections of the rod by compression or screws. All forms of screw couplings are good, as is also the form consisting of a thimble in one section and a spring catch in the other, provided these connections are all non-corrosive.

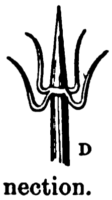


Among the lightning conductors may be noticed an independent, isolated, self-supporting lightning conductor, somewhat as figured in the diagram. Another form of conductor consists of a straight hollow zinc core, covered with sheet copper, and a series of twisted encircling tubes of zinc covered with sheet copper. It is to be noticed here that in the construction of lightning-rods no advantage can be taken of the fact that electricity resides on the surface. A hollow metallic tube is of little value as a lightning conductor. With one exception, the only other conductor worth noticing is a cable composed of twisted copper wires. This is an unobjectionable form of conductor, if

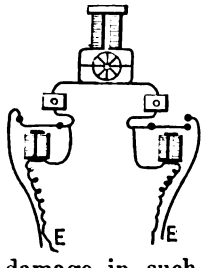
1. *American Meteorological Journal.*

the diameter of the cable be a trifle greater than $\frac{1}{2}$ inch. A good form of conductor and rod is exemplified in one of the later patents, consisting of a flexible conductor, presumably a cable similar to the one previously described, lettered G in the accompanying diagram—in combination with the tube B applied to its upper end, the tip D applied at the upper end of the tube, and the rod A supporting such a tip. One patentee calls his invention by the proper name of the lightning-rod, viz: that of a lightning diffuser or neutralizer. It consists of an electrical conductor placed in a vertical position, and provided with one or more points at its upper and lower ends. These conductors are attached to different parts of the building and have no metallic connection with each other or with the ground.

This is in no sense a lightning-rod, and the writer knows not what its special mission may be. In another patent the gutters of the roof are connected with a ground terminal, consisting of a slitted tube, by an open trough. A hole in the latter permits the rain-water to fill the slitted tube, so moistening the earth at the ground connection. No mention is made of anything in the way of a conductor further than the leader, which is not serviceable. Further, it is obvious that, if the lightning precedes the rain, the design fails of its purpose. As a matter of fact the old saying that "rain follows thunder" is a very true one.



Most of the patents exhibit, if not ignorance, at least a lack of confidence in Ohm's law. Preece's experiments have proved that discharges of the highest attainable intensity conform to the law. As a consequence, no advantage is to be derived from either flat or tubular conductors, conductivity alone being concerned. Faraday long ago pointed out this fact, and in this very connection. Most of the designs patented are poor. There is no originality, little ingenuity and a marked absence of anything calculated to give the impression that the inventors of lightning-rods have any thorough knowledge of the theory and use of lightning-rods. If we turn for a moment to the methods adopted by telegraph companies, electric lighting companies, and other large corporations to whom the question of protection from lightning is a matter of financial importance, we find a better understanding of the matter, and a confidence in their methods and devices, born from experience and knowledge. Edison's device for protecting electric light systems from lightning consists of two conductors extending from each side of the external circuit to the earth. One is of high resistance and the other of low resistance. We insert in these two earth circuits an arrangement for controlling the low resistance circuit by the current in the high resistance circuit. A fusible wire is inserted in the high resistance, and an electro-magnet controlling a circuit-closer, acting upon cessation of the current. In case of lightning, the closing of the low resistance circuit affords a ready ground. The total damage in such a case is the fusing of a few inches of fine wire. The illustration is interesting, because it shows the perfect obedience of lightning to known laws of electricity, and at the same time the facility and safety with which, in intelligent hands, currents of the greatest intensity can be handled.



In erecting a lightning-rod, the question of a good ground inevitably comes up. One or two inches of loose surface soil is not a ground. Further, connection with leaders or gutters, in the great majority of cases, is not a ground. No matter how much the question of a good ground is agitated, the erection of rods, which are decidedly not well grounded, goes bravely on. One of the most curious, or rather startling, instances of this is that of the Sorbonne (the great building of the French university). Sometime in the summer of 1880 six lightning-rods were put up. In September of the same year the building was struck by lightning. It then came out that the ground connections were defective, making rather a suggestive comment on the actual worth of the knowledge of the scientists and government officials, under whose supervision the rods were erected. Professor Tait tells of a British light-house, recently examined, where it was found that "the lower end of the lightning-rod was *jumped* into the solid rock—a truly original form of earth." A well or spring, or flowing water, makes a good earth. A cistern or tank (non-metallic) is not an earth. A rule might be made to consider no earth good until tested. Lightning-rods should be tested. The inspection of these rods is an industry yet undeveloped in this country. There is an ample field for work, and it should prove remunerative. In France this duty is performed by the government.

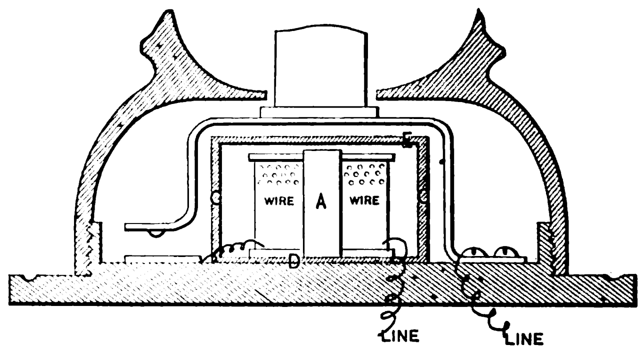
There is one final aspect of the question, not hitherto presented. The question of locality will determine to a great extent the use and nature of the rod. Places distant but a few miles from each other often differ greatly in the relative frequency of thunder-storms. In some localities the erection of rods is imperative, in others needless. Finally, the following further points should be regarded:

1. A solid galvanized iron rod should be $\frac{3}{4}$ inch in diameter, and a solid rod of copper at least $\frac{1}{2}$ inch. These are the best conductors.
2. No sharply bent corners or points should exist on the conductor proper.
3. The conductor should be as far distant as possible from metallic bodies not connected with the ground, or else connected with them.
4. The tops of the rod should be plated, or in some way protected from corrosion and rust.
5. Clusters of points, or groups of two or three, are advantageous.
6. Large trees in the vicinity, being efficient inductors, are of benefit, provided running water does not exist on the opposite side of the building.
7. Chain or linked conductors are of little use.
8. Painting will not interfere with the efficiency of the apparatus.
9. The conductors should not be insulated too well from the building.

CAMBRIDGE, Mass.

A USEFUL INVENTION.

A VERY simple little contrivance, called the Mackenzie Indicator, has been recently devised, which is intended to obviate one of the principal defects in electric bell systems. Under the ordinary arrangement, the person signaling with a push button is unable to determine whether the distant electric bell has responded. By this simple device,



however, the vibrations produced by the circuit breaker of the bell are audibly communicated to the person calling, provided everything is in working order. The principle of the indicator may be readily understood by an examination of the cut. In this case, as will be seen, it is placed inside of a push button suitably constructed, making a very neat

Digitized by Google

and serviceable combination. The soft iron core, A, is fixed to the iron base, D, and is wound with a bobbin of wire, which forms part of the bell circuit. An iron box, C, is placed over this magnet, the lid, E, being close to the core. When the current passes through the wire, the core, A, and lid, E, being the respective poles of a continuous magnet, become magnetized with opposite polarities, and produce a sound which is repeated at every pulsation of the circuit breaker. This is due to the molecular action of the iron, no movable parts being used. The sound produced is sufficient to admit of its being substituted for a bell in quiet offices, where it is desirable to dispense with the annoyance of continuous ringing. It is suggested that it may also be very useful in connection with telephone exchanges, district telegraphs, and railway signals. It is being introduced by Woodhouse & Rawson, London.

THE WATERS RAILWAY SIGNAL.

The importance of electric signals in connection with railway service, has directed the attention of many inventors to the subject. Their aim is to secure that absolute reliability which is apparently impossible under human oversight. A system invented by William T. Waters, of Atlanta, Georgia, comprises some novel and ingenious features. The operation of his block system is very interesting, and is designed to cover every necessary point in connection with the movements of railway trains upon either a single or double track system.

It consists of a series of signaling stations which may be simply posts, with a metallic case containing the necessary mechanism to operate the semaphores. These stations divide the line into blocks, and each is provided with two distinct sets of signals. One set consists of semaphores for each direction, together with illuminated night signals for similar use; the second is a verifying-signal, visible both day and night, operated from either direction, and recognized as a signal whenever seen. The first set consists of four semaphore arms or discs, mounted on rods pivoted within the signal box. Each pair of these discs form an advance and a rear signal. The night signals consist of lights in fixed positions, changed by transparent screens in connection with the day signals. The verifying-signal is a revolving disc by day and a light by night, and the object of this portion of the system is to notify the engineer before leaving a given block, that his advance signal has or has not been displayed at the farther end of the block he is then to enter. The verifying signal is the main signal of the system. The signal mechanism is operated by a reversible electric motor provided at each post, which turns in either direction according to the circuit by which the transmitted impulse may arrive. The operation is entirely automatic, and is actuated by the movement of the train through the medium of a track circuit closer, or an insulated section of the rails, as may be deemed most expedient. The signal posts are connected with an ordinary single wire by means of which the various movements are controlled. The signals are interdependent. One train can in no manner interfere with the signals of another; neither can a train, without adequate warning, approach nearer than the distance of one block to a post whose indications are already controlled by a previous train. These results are attained by a combination of electro-mechanical devices which have been arranged with a view to eliminating all possible elements of danger, and at the same time providing a system which can be introduced at a reasonable expense.

STEEL FOR PERMANENT MAGNETS.

In the manufacture of telephones, magneto call-bells, and certain classes of printing and multiplex instruments, the power and permanency of the steel magnets is essential to excellence. It has generally been considered that the finest quality of steel was best adapted for this purpose. Curiously enough, however, a sample of steel which has been examined in the Patent Office at Washington, while possessing an extreme degree of hardness, appears to be almost wholly incapable of receiving magnetic polarity although subjected to various well-known tests.

A very severe mechanical test of steel is in its use for shoes and dies in quartz crushing mills. M. Furman Hunt, president of the Oxford Gold Mining Co., of Nova Scotia, in his annual report to the directors says:

"The adamantine shoes and dies, made by the Chrome Steel Works, Brooklyn, N. Y. have done admirable service, being replaced only after crushing 3,300 tons of quartz ore. From data of other gold mills at hand, this would seem to show a remarkable capacity for work, and not either on account of the softness of the ore, for on the other hand, the quartz is fairly hard and sharp."

The chrome steel is, however, well adapted for permanent magnets, and is already extensively used for that purpose. All manufacturers of machinery are naturally in favor of such material as secures the best results, and this is especially the case in making light electrical instruments, where the amount of raw material is comparatively small, while its quality is of great importance.

ABSTRACTS AND EXTRACTS.

ELECTRIC RAILWAY SIGNALS.

The Union Switch and Signal Co., of Pittsburg, has, notwithstanding the great depression that has prevailed in railroad business for a year, been in receipt of large orders for immediate delivery, the most of which are from roads which have within the past year or two adopted these appliances, while some are from roads which have heretofore opposed the interlocking system on account of its first cost. Recent accidents on some of the roads, and narrow escapes on others, have driven the managements to the introduction of their appliances.

The completion in 64 days of the contract for the pneumatic system, at Oakland Point, on the Central Pacific road, puts in operation the largest pneumatic interlocking and block-signaling system combined, in use in this country. The Central Pacific is now enabled to despatch trains in safety every half minute, whereas there were before almost daily accidents of more or less extent. This system at this point operates and controls 41 switches and locks, 1 draw-bolt lock on bridge, 110 signals, two highway-crossing bells, 32 bell circuits, 31 electric locking sections, 11 detectors and circuits protecting 13 switches, and is a striking instance of skill and ingenuity as applied to railway safety appliances. This same system is now in use on the Pennsylvania railroad between East Liberty and Wilkinsburg, a distance of about three miles, protecting the intervolved tracks where the traffic is heaviest, and where the speed of trains is greatest. The pneumatic interlocking system, without the block-signaling combined, is also in use at Fortieth street, Chicago, at the stock-yards; at Columbus, O., on the Columbus and Cincinnati Midland; at Brightwood, Ind., on the Indianapolis Union road; at Hammond, on the Michigan Central; at Valparaiso, at the crossing of the Fort Wayne and the Chicago and Grand Trunk; at Bound Brook, at the crossing of the Lehigh Valley and the Philadelphia and Reading; and at Erie, on the Lake Shore and the Michigan Southern.

The pneumatic block signal, without the interlocking, is in use on the Fitchburg road, between South Ashburnham and Fitchburg, and on the New York, Ontario and Western, between Cornwall and Caldwells, 42 blocks, covering 32 miles of track.

During the past three years the Union Switch and Signal Co. has erected, on all the important lines of the

Digitized by Google

country, and on some of lesser importance, over 2,500 levers of Saxby & Farmer interlocking machines. The company expects during the present year to turn out about half of this number, basing calculations on the present rate of orders.

The increasing interest taken in railway safety appliances by railroad managers, railroad commissioners and legislators, as well as the demand of the public at large for better protection of trains at grade crossings, and the large damages generally allowed by juries to parties injured in cases where the adoption of well-known appliances would have prevented the accident, all tend to the speedy introduction of the various kinds of safety appliances, both for equipment as well as for the track.—*Railroad Gazette.*

AN ELECTRICAL PIONEER.

In a biographical sketch recently published in the *Sunday Call*, of Newark, N. J., the following reference is made to the electrical investigations of the late Seth Boyden.

"Soon after Daguerre, in France, succeeded in producing wonderful likenesses upon metallic plates, Seth Boyden studied out the problem, unaided, 3,000 miles away from the inventor, and succeeded in producing the first daguerreotype ever made in this country.

"From this he drifted into the boundless field of electricity, and although at this time a tyro as an electrician he boldly grappled with the lightning, and aided by his intercourse with Prof. Morse, who frequently consulted him upon the mechanical difficulties constantly arising in the way of the success of the wonderful telegraph, he soon became familiar with the subject. Of abstract science he knew but little; he was practical and inventive by nature. But into this new field he threw his whole energy and zeal with good results. As Seth Boyden was deficient in education he labored under many disadvantages. He had not the aid of a familiarity with technical treatises. The big words of scholastic books were constant stumbling blocks to him. But his acquaintance with Prof. Morse and Prof. Henry, of the Smithsonian Institution, in later years, were of valuable assistance to him in giving direction to his fertile but sometimes misdirected ideas. At the same time, his contact with such scientists and savants revealed to him the painful fact how much time and labor he had often thrown away patiently investigating and experimenting upon things which a better knowledge of books would have shown him were already known to the world. He had been often working in almost mental darkness so far as the helps of published data were concerned. But in all his researches and explorations he seemed to be guided by an intuitive knowledge of the existence of the hidden thing which he was determined to reveal. And he never wasted an hour upon any visionary object, only the purely practical and the useful attracted the thoughts and labors of this intensely practical mind. He was, not inaptly, called the "father of the machine business" in Newark. His experiments with the lightning-rod to prove his idea that electricity cannot all come from one direction confirmed his theory."

A TECHNICAL RAILWAY SCHOOL.

The Baltimore and Ohio Railroad Co. has issued an order for the establishment of a Technological school at Mount Clare, Baltimore, for the promotion of a higher course of instruction for apprentices than that now pursued. It is the intention to afford the young men in its employ an opportunity to obtain a technical education superior to the facilities enjoyed by the employés of other similar companies. Students will be divided into the following grades: the first or junior class, of apprentices; the second class, or cadets; and the third, or senior class of cadet officers. The expense of education is borne by the company, in return for which it expects to avail itself of the students' services, at fair salaries for at least three years after graduation. Upon entering the school, they will be paid according to the following schedule: Apprentices 70 cents per day the first year, 80 cents the second, 90 cents the third and $1 the fourth year; the cadets $1 per day the first year, $1.12½ the second, $1.25 the third year; cadet officers, $1.50 per day the first year, $1.75 the second, and $2 the third year. In their appointment, preference is to be given, all other things being equal, to the sons of employés who have been killed or injured in the company's service, and free tuition is given to those only who are sons of employés who have been five consecutive years in the company's service. They must pass a board of examination as to proficiency in elementary studies, and soundness in health. The line of studies to be pursued has not been made public, but the length of the course indicates that the intention is to found a school which will eventually give its graduates a high standing in the field which they are expected to occupy.

CALCULATING RESISTANCE OF ARMATURES.

[38.]—Would you be good enough to explain what is understood to be the *resistance* of an armature. Such, for example, as an ordinary Gramme, in which the end of one coil is connected (by the commutator strip) to the beginning of the next.

For example: an armature has, say, 1,000 feet of wire upon it, the end of each coil or section being connected with the next. The resistance of 1,000 feet of the wire is 0.25 ohm. What is the resistance of the armature?—.25 ohm, .125 ohm or .0625 ohm?

Suppose the brushes to be in position on the commutator and the machine in operation, current will flow by the + brush out to the external circuit, back through the — brush, and through the armature. If it has to pass in series through the whole of the coils forming the 1,000 feet, the resistance must be .25 ohm; but does it not divide at the negative brush and return to the positive in multiple arc, each half of the commutator serving as a conductor and halving the resistance? Again, the distance to be traversed also being halved (500 instead of 1,000 feet) it seems that the resistance ought to be again halved, thus reducing the actual resistance of the armature to ¼ of what would be the resistance, in series, of its wire.

A SUBSCRIBER.

BOSTON, Mass.

[You are right in your understanding of the matter. The resistance of the armature is the resistance, in multiple arc, of the coils in circuit.

As Prof. Silvanus Thompson has shown (*Dynamo-electric Machinery*, p. 50, fig. 39), any ordinary armature of the drum or ring type may be regarded as acting like two voltaic batteries united in multiple arc or parallel, in which case the internal resistance is but one-fourth of what it would be were the cells placed in a single series.—EDITOR.]

THE AMOUNT OF POWER USED FOR ELECTRIC LIGHTING.

[39.]—Referring to a leading article on "Electrical Units" in a contemporary, in which it is stated that at the present moment there is not in the whole world 10,000 indicated h. p. used in the production of electricity, Mr. M. A. Miller, C. E., of Newark, N. J., writes:—"I should like to state that in the United States alone there is a greater amount of steam power used for electric lighting than four times the number of indicated h. p. stated. I can prove that but one of the leading electric light companies of the states, viz., the United States Electric Lighting Co., using the Weston systems, has arc and incandescent lights and dynamo machines running which use—

Digitized by Google

For the city of New York, three stations........2,000 H. P.
Independent plants, including Brooklyn bridge.1,000 "
In different parts of the country, Independent plants.......... { Arc lights...5,000 " / Incandescent lights.....5,000 "
Local stations at Boston, Manchester, Providence, Newport, Rochester, Newark, Philadelphia, Baltimore, Washington, Charleston, Toledo, Ohio, and many other places..............10,000 "

Making a total for one electric lighting company alone of................................23,000 H. P.

That this statement is rather below than above the actual number of h. p. used for the Weston systems may simply be proved by the fact that there have been built up to the present time more than 2,000 Weston dynamo machines, requiring in the average each about 10 h. p. The United States Electric Lighting Co. has formerly also built about 500 Maxim machines, absorbing about 6 h. p. each, giving thus a total number of h. p. as stated above. Taking the Edison, the Brush, the Thomson-Houston, and half a dozen other electric light companies, into consideration, I think 40,000 h. p., used for electric lighting purposes in the United States alone, would rather be a low estimate than otherwise."

QUESTIONS AND ANSWERS.

[69.]—**Experimental Storage Battery.**—J. S. L., of Pittsburg, says:—I have some 16 c. p. incandescent electric lamps, requiring a current of 110 volts, $\frac{9}{10}$ ampère, that I wish to use, and intend making a storage battery for that purpose, similar to one mentioned in THE ELECTRICIAN AND ELECTRICAL ENGINEER (page 14, volume iv., "New forms of primary and secondary batteries"), as being composed of lead pipes rammed full of oxide of lead, etc. Would a battery constructed on this plan, weighing 150 pounds, divided into six cells of 25 pounds each, be large enough for current required? And would a bichromate battery of 12 cells, giving a current of approximately 24 volts, 1 ampère, at terminals, be sufficiently strong to charge storage battery in 10 to 15 hours with a current capable of running lamps four or five hours? **Ans.**—You can obtain but two volts from each cell, therefore for a 110 volt lamp, 55 cells would be required; but they can be very small if you need but .9 of an ampère. The battery you propose would not, therefore, produce the required results, neither would the primary charge it. As a rule, one square foot of surface per ampère will be a practical guide. For experimental purposes, the form you desire to adopt should be satisfactory.

CATALOGUES RECEIVED.

The Bennett Telephone and Electric Co. of Indianapolis, issue a neat little illustrated catalogue, describing their various appliances to be used with the Bennett non-electric telephone. It is especially noticeable for containing no extravagant claims as to what the instruments will do, but is apparently based on facts.

Mitchell, Vance & Co., of New York, have issued a large catalogue copiously illustrated with beautiful phototypes of their elegantly designed fixtures for incandescent lighting. The goods represented are adapted to the fittings of the different electric lighting systems, or for both gas and incandescent lamps. Distant customers will experience no difficulty in making their selections from this book, the plates being reproduced from photographs and the dimensions of the fixtures given in every case.

CORRESPONDENCE.

NEW YORK AND VICINITY.

The Underground Commissioners in New York and Brooklyn.—The Electric Headlight Appears in the East.—The Rival Ticker Systems.—Fire Alarm Systems, Old and New.

WITH the appointment of the three commissioners to enforce compliance with the Daly "underground" law, interest in the subject has to a great extent died out, although there appears to be little confidence that the interment of the wires will be hastened under the supervision of such experts as Jacob Hess, Charles E. Loew and Theodore Moss, who have been selected to determine what wires it is "practicable" to bury. The commissioners for the city of Brooklyn under the same act are gentlemen of recognized scientific and legal training, and have entered upon the work of organization with the idea of at least ascertaining the actual difficulties which confront them. At their first meeting the secretary was instructed to notify all electrical companies in the city of the organization of the board; to request from each of them its plan for placing its wires underground, or its reasons why they should be permitted to remain where they now are. These documents are to be accompanied by full details of the location of poles and conductors, and submitted by the 12th of August. Appreciating the difficulty of the situation, the commission proposes to permit the temporary erection of such wires as may be necessary, where they will not conflict with the future general plan of the underground system. In order to obtain all possible information upon the subject of subterranean electrical work, the following resolution was adopted:

Resolved, That this board invites from all persons or corporations interested in the adoption of a general underground electrical system, plans or suggestions in writing, and will grant special hearings in cases where after examination of the papers thus submitted it shall deem such hearings advisable.
That all communications intended for the board should be addressed to the Board of Commissioners of Electrical Subways, City Hall, Brooklyn.

A conference was subsequently held with the officers of the New York and New Jersey Telephone Co. regarding the wires in Washington street, but no decision was arrived at. It is said that hundreds of "best" systems have already been presented to the board. It is very probable that the technical knowledge of the Brooklyn commissioners will be of considerable value to the amateurs who are acting in the same capacity in this city. The careless manner in which this whole matter has been handled in the Legislature is proved by the recent announcement that there is some doubt as to whether funds are legally available to provide salaries for the commissioners, owing to a defect in the law.

The first appearance of the electric locomotive headlight in the East, was on one of the Lehigh Valley trains between Jersey City and Easton, on the 4th of July. It has proved a decided sensation along the line of the railway; crowds assembling at various stations to see it pass. The engineer is very much pleased with it, and its power certainly far exceeds the ordinary oil lamp. Its very brilliancy, however, is one of the objections to its general adoption on double track lines, for it is said to be impossible at times for the engineer running in the opposite direction to distinguish the switch signals ahead of him on account of the glare from the approaching arc lamp. As it is of far greater importance that every signal should be visible than that possible obstructions on the track may be detected, it appears somewhat doubtful whether the electric headlight will receive immediate official approval.

The efforts which have been made to deprive the Commercial Telegram Co. of its privileges in the Stock Exchange have not as yet proved successful. At a meeting of the governing committee on the 17th it was decided by an almost unanimous vote that the Commercial was entitled to equal privileges with the Gold and Stock company. Active preparations are being made for the introduction of the new Scott printers, and with their successful adoption, which is a matter of but a few weeks, the Gold and Stock company will be so far in advance, from a mechanical as well as a financial point of view, that it need have little fear of rivalry for many years to come. When this change is made, the operating room at 195 Broadway, and the carbon battery room at 8 Dey street, will both be vacated.

The fire departments of our larger cities are remarkable examples of the perfection to which mechanical skill and the faithful service of disciplined and intelligent men may bring a service in which every member is stimulated by the thought that merit will surely bring its reward. The fire alarm telegraph and the steamer have been such prominent factors in the modern system of fire extinguishing, that watchmen in fire towers have been looked upon as merely sentimental relics of the old volunteer service. That they are really useful, however, appears from the annual report of the Chicago fire department, in which it is stated that at least one-third of the actual fires in that city last year were discovered by watchmen in the old-fashioned towers. Such a record should be a strong argument in favor of the reestablishment of the tower system in every city, as an auxiliary to the fire alarm telegraph, which is occasionally deranged by severe storms.

The Lowell Police Telegraph System.—Association of Electrical Linemen.—Serious Effects of Lightning in New England.—Distance at Which Thunder May be Heard.—Electric Lighting for Peru.—The City Fathers Too Extravagant in Using Telephones.—Proposed Electric Railway Privileges.—The Postal Company Ready for Business.—Resignations of General Manager Vail and Assistant General Manager Madden.

THE city solicitor of Lowell has presented an opinion to the committee investigating the subject of the introduction of the police telegraph in December, mentioned in a previous letter, and

Digitized by Google

finds that the contract made by the committee on police and signed by the Mayor is not binding on the city. The committee has demonstrated that the system is impracticable, and that the price for it, $2,200 per annum for five years, is exorbitant.

The line-men employed in this city recently held a meeting for the purpose of organizing a mutual benefit association. There are so many electrical companies here that there ought not to be any serious difficulty in the matter.

The intense heat during the first of the month was followed by serious thunder storms throughout most of New England. Churches and other buildings towards which the fluid usually shows partiality did not escape; the damages being severe all around.

On Mount Washington, July 3d, a bolt of lightning entered the signal station at noon causing some damage, and badly injuring a railway employé James Camden. Both legs were paralyzed. The injured man was carried to the base of the mountain, and his feet placed in the ground. His friends had a theory that he was fully charged—not however as the good old hymn has it "A charge to keep I have," but one to be got rid of—and that the electricity would escape to earth when he was thus grounded. It is said the treatment proved successful to some extent. On the mountain after the storm the ground was covered with hail to the depth of an inch or more, and appeared snow-capped.

On the 9th a severe thunder storm passed over the city of Lowell, the lightning doing considerable damage. Telephone wires were struck, setting fire to the tower of the Telephone Exchange. The lightning arresters were not of sufficient conductivity to carry off the electricity and the wires were destroyed, completely interrupting the system. Not much injury was done below the tower, beyond burning a coil or two and giving the operators a sensation. The arresters probably saved the switch-boards and connections. It was but a few hours work to get in running order again.

An electric light trimmer while adjusting a lamp in East Boston on June 30th, met the current when it was turned on and received the full shock. When it struck him he was stunned, and losing his balance fell across the bar at the top of the light stand —and his wrist coming in contact with the wire was severely burned—causing however, no permanent injury. "No fault of the owners, the man only to blame."

Among the papers read at the 120th corporate meeting of the Boston Scientific Society, was one by Mr. H. P. Curtis on "Acoustics of Thunder." He said, that "contrary to the assertions of physical treatises, which hold that thunder is audible only 10 to 15 miles or possibly 18 miles from the generating flash, as the result of 10 years observations in Europe and here; he had heard thunder at a distance of 100 miles from the flash. Other observers had noticed flashes, and by timing the interval between flash and thunder, a distance of 150 miles was obtained."

A company, composed in part of gentlemen of this state and Connecticut, and in part of citizens of Peru, has lately been formed for the purpose of supplying the republic of Peru with the electric light, and will operate under exclusive grants from the Peruvian government for a period of 20 years, during which time all their electric lighting apparatus, machinery and other electric appliances will be admitted into the ports of that country duty free. These grants extend to and include the eight principal cities, viz.: Lima, Callao, Arequipa, Puno, Cuzco, Truxillo, Cazamara and Puira. During July a plant of 90 arc lights, from the works of the Thomson-Houston company at Lynn will be shipped to Peru. The company has already, it is said, received orders for apparatus from other cities and towns in Peru, but, under the terms of the grant, the electric light must first be introduced in Lima, the capital. Lima pays about $150,000 a year for gas, for which $3.20 in gold per 1,000 feet is charged. It is calculated that it will take 360 arc lamps to light the streets of that city.

At the meeting of the Board of Aldermen on the 7th inst., the Mayor sent in a communication announcing that the use of telephones in the city had cost $12,881.38 during the year, and that every department acts independently in their use. He is satisfied that there could be a saving of $7,000 to $8,000 per year if the telephone system was placed in the fire alarm department under the control of the superintendent of that department, thus making a saving of $100 per year on each telephone. The communication was referred to the committee on fire department. The following petitions were presented and referred: Bently-Knight Electric Railway Co., for leave to excavate the streets occupied by the tracks of the Metropolitan railroad, for the purpose of putting in operation its method of operating tramways; Boston Electric Light Co., for poles on Leverett and Brighton streets. An order was passed authorizing the Union Electric Light Co. to erect 12 poles in Lamson, Maverick and Bremen streets.

The Postal Telegraph Co. threw open its doors to the public on the evening of the 16th inst. at No. 4 Arch street, in the offices of the Commercial Cable Co.

Considerable surprise was manifested on the announcement of the resignation of Mr. Theo. N. Vail, general manager of the American Bell Telephone Co. He has been so thoroughly identified with the Bell Telephone company, that people had become to think that their interests were indissoluble.

Mr. Vail's history is characteristic of the young American of this age, when backed by energy and business ability. He was born at Malvern, Ohio in 1845. In 1865 he was in the employ of the United States Telegraph Co. In 1867 he was an operator in the Canal street office, at Morristown, N. J., and afterwards transferred to Newark; and in 1868 he turns up as an operator on the Union Pacific Railroad. In 1869 he entered the service of the government as mail agent between Omaha, Neb. and Ogden, Utah, at a salary of $1,000 per annum; and the same year was married and settled at Omaha, from which place he was transferred to Washington to act in the capacity of clerk, and was from time to time promoted. In February 1876, upon the death of Genl. Bangs, general superintendent of the railway mail service, Mr. Vail was appointed his successor—a position he held until his retirement to engage in the telephone business. Mr. Gardiner G. Hubbard was the first president of the Bell Telephone company, and having been connected with the United States post-office department, he there met and recognized Mr. Vail's ability, and through his solicitation Mr. Vail accepted the position of general manager of the Bell company.

Mr. Vail's capacity was fully proved in the early and severe struggles of the Bell company to throw off the Western Union entanglements, and to place his company on a business basis.

In whatever field of labor he may choose in the future, Mr. Vail will have the good wishes and cordial sympathy of a host of people to whom his name has become so pleasantly familiar by telephonic associations—and much more by personal association.

Mr. John E. Hudson, who succeeds Mr. Vail, while not so generally known, has been an associate in business with Mr. Vail for three years or more, as counsel and resident attorney for the company, and is entirely familiar with all the business of the company. Mr. Hudson is somewhat retired and grave in his demeanor, though he has a genial and wholesome disposition, and is in all respects a business man and a man of ability, and a worthy successor to the position of general manager.

Since writing the above, I hear of the resignation of Mr. Oscar E. Madden, who has been for so long a time ass't.-general manager of the Bell company. Mr. Madden entered the telephone service in the year 1878, before the telephone territory had been taken up. He was largely instrumental in the forming of the sub-companies, and has been to a great extent identified with the details of the business of the company; and no man has been more widely known in telephone circles. It is reported that Mr. C. Jay French, who has been a special agent of the Bell company at Chicago for some months will assume the duties vacated by Mr. Madden. It is an old saying "Speed the parting, welcome the coming." The telephone business remains, and has able and strong heads to perpetuate the work so ably commenced.

BOSTON, July, 18th 1885.

CHICAGO.

Experimental Test of Bare Wires Underground.—Evading the Indiana Telephone Law.—Incandescent Lamps for the Cook County Buildings.—The Legislative Bribery Story.—Special Electric Devices for Hospital Use.—Incandescent Lighting in the Theatres.—Ozone as a Disinfectant.—Serious Storms Throughout the West.—Criticism on Prof. Forbes's Distribution of Electricity.

In the last number of this correspondence mention was made of a test of the Dorsett underground conduit, which proved conclusively the insulating properties of the compound. The test, which was but an experiment, consisted in placing naked wires in one of these underground conduits for carrying electric light currents. The plant of 40 lights is still running successfully. While this proves conclusively that such wires may be safely run in the manner indicated, it was not intended to continue the arrangement permanently. The installation of the wires spoken of, where they are liable to dampness or other interference at the terminals of the pipe, was very complete, and the insulation rendered very thorough, by the following process, which is given for the benefit of those interested: The wire, before drawing in, was thoroughly taped from the union between the naked copper and the outside wire, for a few inches at either conduit terminal into the pipe. A cork, slit to receive the wire, was then placed upon this latter, and crowded into the end of the conduit about an inch. Then this counter-sunk space was filled with a compound which completely insulated the wire at the terminals of the tube, and made these air, water, and gas-tight, at the same time.

The Central Union Telephone Co. is earnestly combating the unjust law recently passed by the Indiana legislature. Their method of evasion, by charging for the use of lines, switch-boards, etc., is held to be a violation by the advocates of the law; while, on the contrary, the company insist that while they are making these charges, they violate no law or justice, inasmuch as only telephone rentals are governed by the late enactment. All new contracts are made for a period of three months only; and should the law be held to be constitutional, the company will quietly withdraw from the state, and remain out until the solons shall have come to their senses.

Digitized by Google

A contract was recently entered into between this county—Cook—by its commissioners, and the United States company, by its Western manager, Mr. C. C. Warren, for the lighting of the county buildings by incandescent lamps. The following are the proposed plants:

County building	1,200
Criminal court	350
County infirmary	250
Asylum, old portion	320
" new wing	65
County hospital	1,300
A total of	3,485

lights. The successful bid for the above plants, which includes an expert's services for one month after completion, was $79,800. The Edison company's bid for the same work was $83,000.

Quite a hubbub was created in our state legislature during its last days of imbecility, on account of an affidavit of which the following is a copy:

"Frederick H. Tubbs, being first duly sworn, states that he is district superintendent of the Western Union Telegraph Co. at Chicago, his district covering most of the states of Illinois and Iowa, and that during the early part of the present session of the legislature, representative John H. Baker twice called at his room at the Leland hotel, Springfield, Ill., and offered to take care of (kill) his own bill, House bill No, 178, and stated that he could in all probability do the same for any other bills prejudicial to the interests of the Western Union Telegraph Co.

"He particularly mentioned Linegar's bill (144), taking —— per centage on gross receipts. He asked, as compensation, $500 at the time, and probably 'two' at the close of the session. He afterwards explained that 'two' meant $2,000."

The representative mentioned denied the statement of Tubbs in toto, and in the discussion ensuing and recrimination that followed, the main issue was lost sight of entirely, and both the proposed bills regulating the telegraph and the telephone enterprises, like small dogs in a general canine rumpus, escaped under cover of the dust and howls.

The Edison company, which lately placed a plant at the Wauwatosa insane asylum, near Milwaukee, in accordance with a request from the authorities there, has introduced a novel arrangement for regulating the light of the lamps in the hospital and other places where a full illumination is not constantly needed. Mr. Chas. Wirt, the company's electrician here, accomplished the desired result in a very simple and effective manner. The apparatus consists of five resistance coils of varying strength, which are cut in or out of the lamp circuit by means of a switch. A sixth contact cuts out the light entirely. The whole is mounted upon a small board which can be fastened on the wall or wainscoting, and is about 6 x 8 inches. The coils are inclosed in tin, and outside this is a wire cloth grating. Mr. Wirt also proposes using these as heaters for the patients, by attaching them by a flexible cord, so that they may be utilized in a bed, chair, or as a footstool. By throwing a portion of the current—say half a c. p.—through the coils, a gentle, constant heat is engendered, which requires no attention and needs no renewal, like a hot brick or a water bottle.

McVicker's theatre has been entirely reorganized throughout, and is now one of the most beautiful theatres in existence; 1,200 incandescent lamps illuminate the internal portion of the structure, and three outside arc lamps guide the pleasure seeker to this palace of Thespis.

Next in order among the list of places of entertainment to be lighted will be the "Battle of Shiloh," which is to be illuminated by the Excelsior people, and will be ready for business on the 1st of August. Almost immediately afterward, the Chicago Opera House, lighted by something over 600 Edison lamps, will put forth its claims to the amusement-loving citizens of Chicago and the strangers within her gates.

Speaking of cholera the other day, a well-known electrician of this city said that he had great faith in ozone as a disinfectant, and that if the dread scourge should visit the city this or next year, he had about made up his mind to purchase a good static machine for family use—for the good lady of the household to play with, and the younger members to experiment with, during the stay of the unwelcome visitor. Certainly, if there is the value in ozone which is ascribed to it, there should be a good demand for these instruments under such circumstances. Aside from its value in a scientific point of view, the confidence it would inspire in a family ought certainly to make it valuable, and a quite limited number of druggists' and doctors' bills would be sufficient to pay for one. It is a good time to test it, when cholera is around.

The entire Western country has been the scene of most violent storms, varying in magnitude from heavy thunder showers to cyclones and tornadoes, for several weeks. Chicago has been favored with several extensive exhibits of this nature. On the 27th of June we were treated to one of these displays, which played some funny pranks at Cheltenham beach, one of our "sea-side" suburbs. Lightning in this case struck a summer cottage, running down the chimney; thence dividing, a portion struck the contents of a gentleman's trousers-pocket, and coursed its way to earth through one leg of his garment, scorching this and ripping off the sole of the boot. The shock received was severe, but not fatal.

Another severe storm, which extended over a large portion of the northern states, was particularly severe in Wisconsin and Minnesota, tearing its way through the former state in a diagonal line between the southeast and northwest portions of the state.

On the 16th inst. still another of these fearful storms swept over portions of southern Minnesota and Dakota, while parts of northern Illinois and portions of Wisconsin also suffered. At Highmore and Holabird, Dak., the storm was classed as a cyclone, and the latter town was almost torn to pieces. Few lives were lost. Mr. E. B. Thompson, residing near Highmore, was picked up by the whirling monster and dropped, with his neck broken, about an eighth of a mile away. In the western belt of towns in Dakota, a district of not less than 18 miles wide, reaching into the Cheyenne valley, was visited a few days since by a storm which wound up with heavy hail, and destroyed great quantities of growing grain and other produce. Hail also fell in large quantities during the storm of the 16th, demolishing crops and window glass, at Manuel, about 10 miles below Grand Forks, Dak. The storm divided after this freak, and a portion of the cloud passed southwesterly, but the heavier part took the old beaten track through Polk county, Minn. Throughout its line of march the most vivid illumination was almost constant, and the rolling thunder was both fearful and persistent. A correspondent at Bismarck says:

"There was a wonderful display of lightning here last night (16th). The entire city was on the streets and in doorways watching the storm. The flashes followed so fast that people read newspapers on the street. It was the grandest scene ever witnessed in the country. The heavens were a continual blaze, and there was constant rumbling thunder; yet stars shone overhead."

The man has again made his appearance who offers to mix some chemical with feed water for boilers, to obtain steam at a lower temperature than 212°, and so save fuel, "you ll understand." He and the bi-sulphide of carbon enthusiast, the perpetual motion fellow, and the man who runs arc lamps with a battery, are a quartette that deserve a place in the front ranks of a first-class institution for the care of the feeble-minded; for, like the dying girl in the old song, altered to fit the occasion—

"They are almost there,
Or they soon will be,
When relief will come
To you and to me."

Popular Science News recently published a few words on the subject of steam power, which is worthy of being repeated in this connection. It says:

"The fallacy of all such schemes lies in considering that the steam or vapor developed in a boiler is the source of the power, when really all the force exerted by an engine is derived from the fuel in the furnace, and the steam or vapor simply serves as a means of conveying it to the pistons and wheels of the machinery."

There the truth lies in a nutshell, and the simplest mental pick may abstract it.

A curious source of error in weighing delicate quantities has latterly been discovered by a German, Mr. Hennig, of Wurzburg. Owing to a supposed error in results, Mr. Hennig made careful investigation, and found that the scales he was making use of were affected by the electrical condition of the rectangular glass shade which covered and protected the balance. The lever of the balance carries small sliding weights, called "riders," by which to obtain more delicate divisions than can be arrived at by arbitrary weights in the scale pans, and he found that wiping the glass shade above these produced sufficient electricity to raise them from the beam. Rubbing the shade lightly with a linen dusting cloth displaced the zero pointer several lines, while with silk or woolen cloth this error was materially less. The amounts of error thus engendered is shown as follows: After the first rubbing of the shade the electrical charge held balanced 600 milligrammes, and at the end of two hours still balanced a weight of 10 milligrammes; while with silk or woolen rubbers, under identical conditions of the atmosphere, the charge was balanced by 150 milligrammes and 70 milligrammes, respectively. The charge was dissipated by a Bunsen flame, instantaneously applied. Mr. Hennig purposes remedying the difficulty by attaching to the under surface of the glass shade a metallic grating with an earth connection, so that an accidental charge will be disposed of before it can do mischief.

In the July number of THE ELECTRICIAN AND ELECTRICAL ENGINEER, an article by Prof. Forbes, on "The Distribution of Electricity," is at variance with the results obtained by practical electricians here. He makes the statement that that form of multiple series installation, known as the three-wire system, will give a saving in copper of only 25 per cent. They claim that despite the endorsement of Dr. Hopkinson, the professor is wrong, and the "American financiers" are right, and base this assertion on the following: It is usual in America to figure electric light conductors as a certain per centage of the total resistance. The relation of the size of conductor to the current to be

carried is a separate consideration, not affecting economy, except where the size of wire approaches the limit of safety—which only happens when circuits are quite short. Now, take the case of four lamps and one dynamo, each lamp having a resistance of 1 on the multiple system, our joint resistance will be ¼. If we put the same lamp in multiple series with two dynamos, the joint lamp resistance will be 1. We have here multiplied our lamp resistance by four, used the same lamps, and given them the same energy. Clearly, then, we can multiply the resistance of our mains by four and lose the same per centage of energy in the conductors The third wire cuts no figure in the calculation, and its size is determined by the character of the service. Practically one-half the size of the + and — mains is ordinarily sufficient for the third wire.

CHICAGO, July 20, 1885.

WASHINGTON.

Destructive Fire Originating in an Electric Lighting Station.—The Scientific Opinion of the Fire Marshal.—The Central Plant to be Enlarged.—The Cooperative Lighting Scheme Abandoned.—The Philadelphia City Fathers Seeking Subterranean Information.—The Electrical Companies Beset With Difficulties in Running Wires.—Prospective Extensive Organization of Telegraphers.

ANOTHER destructive fire stands charged to the electric lights. It is true that under similar circumstances the same result would have been experienced in a cotton factory, planing mill or any other mechanical establishment. In other words the fire was caused by friction in the machinery and electricity had nothing to do with it. But it occurred in the works of the United States Electric Light Co., and with the unthinking public the electric light is charged with the destruction of the property that resulted.

About 8 o'clock P.M. on the 17th inst. a fire broke out in the engine room of the U. S. E. L. Co. which is located in the *Post* building, and spreading with great rapidity was not checked until it had destroyed four newspaper offices located in the same building, viz.: *Post, Republican* and *Critic* (daily) and the *Hatchet* (Sunday). The Sunday *Herald* and Sunday *Gazette* in adjoining buildings narrowly escaped. The story of the fire is graphically given by our worthy fire marshal as follows:

> The fire apparently originated from a heated journal on the main shaft, on which the person in charge emptied a can of oil, which immediately took fire, and was communicated to the broad leather belting running over the drum of said shaft and in close proximity to the journals. On this belting the same person threw water, and owing to the electricity in the leather the fire was spread.

It is to be regretted that he did not go into detail as to the manner in which the water and electricity from the belt combined to spread the fire, but as electricity already stands charged with the fire it is a matter of interest only to scientists.

The loss of the U. S. company will amount to about $50,000, insured for about $15,000. Its directors held a special meeting the morning after the fire and took steps for a speedy replacement of the machinery destroyed. The engines, boilers and other property of the Brush-Swan company, which has lain idle for several months, was leased, and permission to connect the works by air lines temporarily was obtained—four dynamos secured from the parent company in New York—and in five days from the fire the lights were all going again on the streets and in the departments. The company was able to do this without borrowing or issuing additional stock. Arrangements were at the same time made for enlarging the plant as soon as the necessary machinery can be manufactured.

Messrs. Lansburgh & Bro. have introduced the Thomson-Houston light in their extensive establishment and are much pleased with it. The idea of making a coöperative affair has been abandoned—Messrs. Sox & Co., who were to join in the enterprise, are now putting in as a private plant the Hochhausen Excelsior light in their new structure corner 7th st. and Pennsylvania avenue.

A delegation of the Philadelphia city councils visited Washington one day last week for the purpose of examining into the underground systems used here. They were shown every attention by manager Marean of the Western Union, supt. Miles of the Fire Alarm Telegraph, and general manager Bryan of the Chesapeake & Potomac Telephone Co. They went away with a good opinion of the Waring cables for municipal purposes but not fully converted to a general burying of all electric wires.

The Baltimore and Ohio Telegraph Co. propose to lay their wires underground from the depot where their air lines will terminate to their uptown offices, a distance of about a mile and a half. Negotiations are now pending with the commissioners as to the route.

In the matter of the injunction suit against the Western Union Telegraph Co. to restrain them from maintaining a new line of poles on 7th st., in which is involved the question of the commissioners control of the streets, both, or rather all three sides, are busily engaged taking testimony before a U. S. commissioner preparatory to a final hearing before the full court some time this fall. The telephone people are waiting the decision and will lay no more cables until their right to put up distributing poles in the alleys in the centre of a block is established. This permission was given them by the commissioners in consideration of the substitution of underground for overhead wires along the streets.

As matters now stand the companies find it less difficult to keep their poles where they are than to attempt any change that may bring them before Judge Hagner. The house-top wires seem to be the only ones beyond the reach of the courts and commissioners and even these are not always safe. One by one wires had been strung over the Treasury building by telegraph, telephone, electric light and messenger companies until a regular web was woven over the roof of the building. This appeared so unsightly to Secretary Manning that soon after coming into office he notified all the parties interested that unless their wires were removed by the first of July they would be cut away. The telephone people in carrying out their cable scheme had underground wires ready by the time fixed, but had left about a dozen dead wires on the building. The others paid no attention to the order and were somewhat surprised when the day named came to find every wire cut loose and coiled up to the nearest bracket or pole with the insulators, frames, brackets, etc., piled up alongside of them.

The operators generally are much pleased to find that the existence of the Bankers and Merchants' and the Postal Telegraph is to be prolonged for a while at least, regarding their competition as to some degree a safeguard against a wholesale reduction of wages. Their demise would probably be the signal for the formation of a league or union more formidable than any the Western Union has heretofore encountered. The other trades unions are beginning to see in the telegraph a weapon of great power, if properly handled, and one that can be wielded at comparatively small cost when a question involving the general interest is at issue.

WASHINGTON, July 23, 1885.

PHILADELPHIA.

Excellent Prospects of the Novelties Exhibition.—The New Telephone System of the Fire Department.—The Clay Commercial Telephone Plant Sold at Auction.—The Wire War.—The Western Union Main Operating Room Burned Out.

SPACE at the Novelties Exhibition, to be held under the auspices of the Franklin Institute, is rapidly filling up, and the indications are that applicants will be very much cramped. The building is undergoing a process of reconstruction in the inside since the dynamo and incandescent tests were finished, which have been going on there, until recently, since the close of the electrical exhibition. The buildings will be greatly improved, and the space for exhibitors made suitable for their convenience. The committee on exhibitions has been daily in receipt of applications from exhibitors for space. An interesting feature will be (for the first time at any exhibition) the complete exposition of the capabilities of "water gas." It will be demonstrated how from a single line of pipe laid through a city, the inhabitants may supply themselves with heat, light, and power for all purposes, at a smaller cost than with the present methods. Another instructive feature for which arrangements have been made will be a complete and extensive exhibit of the art of silk culture, from the egg of the silkworm to the finished products of the loom. This exhibit will be made by the Women's Silk Culture Association.

The Feister printing press will also be among the extraordinarily remarkable of the exhibits. This will be the first time that this press has ever been seen in public. The press prints from an endless roll, on both sides; folds, pastes and covers the printed sheets, and turns out pamphlets at the other end bound and ready for mailing, without any hand work whatsoever, at the rate of 5,000 per hour. Another of these interesting exhibits will be Mr. Holland's process of working and manipulating the rare metal iridium. This process is an important one. It solves completely the problem of fusing, casting, dividing, drilling, grinding, and the other workings of the most refractory and hardest of all metals. In addition to the exhibitions of Professor Lowe and the Siemens, the Albo-carbon gaslight, which presents a novel mode of enriching ordinary coal gas by the use of naphthaline, a hydro-carbon, which is produced in large quantities as a by-product in the manufacture of coal gas, will be on exhibition. Otto & Clark will show their latest devices in gas engines and domestic motors. Among the miscellaneous exhibits, the cyclostyle, a new process of multiplying the impressions of letters and drawings, will be shown, together with scores of many others of equal worth. During the exhibition the machinery will be kept constantly in motion.

Within a few days past superintendent Walker, of the city's electrical department, has introduced a telephonic system of fire alarms which will greatly enhance the efficiency of that service. The object of the new system is to prevent mistakes which are liable to occur with the ordinary electrical apparatus in transmitting alarms. It acts independently of the old method, and comprises seventy miles of wire connecting each fire engine and truck house with the patrol stations, chief engineer's office, and the electrical department. There are from three to

Digitized by Google

seven engines in each of the eleven circuits, and the chief engineer can go to any box and communicate with any engine house and can order any particular engine or hook and ladder company to any locality. The tests made were perfectly satisfactory. Engine houses in Manayunk (ten miles away from the central station) were called up and spoken to, as were also engine houses in Chestnut Hill, Southwark, and other parts of the city. Telephone messages from the central station pass through the main office, but messages from the engine houses do not reach the central station until after they have been received at headquarters. At 6 o'clock in the morning, and at noon, the exact time will be sent to all the engine houses over the new wires. The system cost $1,900 less than the price at which the Bell company agreed to furnish instruments for, and will save thousands of dollars each year.

A constable's sale of the effects of the Clay Commercial Telephone Co. used in the operation of the exchange on the sixth floor of No. 302 Chestnut street, was held on July 7th. The sale was to raise money for rent, amounting to $333.35, which was due and unpaid. Superintendent F. W. Smith said that the company was in good financial condition, owing not more than $5,000 in the city, but that the directors, in view of the uncertainty of affairs pending the decision of the court in the suit brought by the Bell company for alleged infringements of patents, were unwilling to put more money into the concern.

The instruments and attachments sold were worth, according to Mr. Smith's estimate, nearly $10,000 to the company; but as only $50 was realized at the sale, it is quite certain that they were worth very little to the general public. Exit the Clay Commercial Telephone Co. Next!

Operators of the Bankers and Merchants' Telegraph Co. found something wrong with their instruments about 10 o'clock on the night of July 10th. First the operator who was sending to Baltimore noticed the sudden stoppage that indicated a break in the circuit, and then at intervals of an hour the New York wires refused to work, the wire to Pittsburg broke down, and then, one after another, the extra wires which had been brought into service to those places, gave way also.

The Bankers and Merchants' company here operated all the old American Rapid wires, and in addition, a number of their own. They had four wires to Reading, originally the property of the Lehigh Telegraph Co,, and four American Rapid wires to Baltimore, which came into the city past the testing station near Darby. These wires went down first.

There were four Rapid wires to Pittsburg, and six Bankers and Merchants', all of which were cut west of Harrisburg. Seven Rapid to New York, and 22 Bankers and Merchants' on the same poles, between which a discrimination was made, and the Rapid only cut. Single wires to Kensington and Broad street, both Rapid, were cut. The line from Baltimore to Harrisburg was also cut south of York.

By the crossing of an electric light wire with one of the telegraph wires leading into the operating room of the Western Union office, on the top floor of the magnificent Mutual Life building, at 10th and Chestnut streets, at 2:15 A. M., July 18, the switchboard, holding over 400 wires, was set on fire and the entire office burned out. Night manager Louis D. Maize was just in the middle of a despatch from New York when he perceived a blue flame among the wires. He sprang to the switch-board and began cutting out the burning portions, but the flames gained rapidly and the woodwork around the wires was on fire in a few moments. An attempt was made to use the fire extinguishers provided for emergencies, but they would not work.

The engines arrived within a very few minutes after the discovery of the fire, and the flames were then bursting from every window of the large operating room, leaping in long tongues over the sloping Mansard roof of the building. Night manager Maize tried to save some of the furniture of the office, and escaped from the blazing room with some slight scorching.

Within three minutes after the switch-board was discovered to be on fire, the entire room was filled with a volume of roaring flame.

The whole plant of the main operating room was destroyed, and an official of the Western Union said that $10,000 would hardly cover the loss on instruments, furniture and fixtures.

After the firemen got their ladders up and brought streams to bear on the flames, the fire was quickly gotten under control.

While the fire was raging under the Mansard roof, manager Maize climbed upon the top and connected an instrument with a wire to New York. The message which he was engaged on when the flames spread through the operating room, was finished.

PHILADELPHIA, July 18, 1885.

SAN FRANCISCO.

An Inspection of Apparatus by an Eastern Electrician.—Improved Condition of Duplex and Quads.—A Further Inspection Outside of the Electrical Field.—The Mysteries and Miseries of Chinatown.—A Sewing Machine Motor Service.—Dr. Keith's Electric Railway.—Rumored Changes in the Western Union Service.

THE advent of Mr. Gerritt Smith on this coast caused considerable of a flutter in telegraphic circles—for his fame—as well as his modesty, preceded him; hence from Mr. Smith much was expected and much good has he done. It is difficult to work a quad on a wire which embraces at different parts, three gauges, viz: 6, 8, and 9, as well as being poorly insulated, yet Mr. Smith's three coil relay enabled us to do it (at least for a day or two), and it may be tried again, when only one wire is left us, till then we find it hard enough to work duplex to Ogden. Sometimes the quad on a No. 6 gauge wire is used between Virginia City and Ogden, and two duplex west of Virginia to San Francisco; even in this way we find much trouble in getting Ogden clearly. Whether, this is caused by bad batteries or poor attention, is for electricians to determine, I am not an electrician; but I do say, an occasional visit from such men as Mr. Smith would be productive of an infinite amount of good, by obviating unnecessary profanity on the part of exasperated operators.

With Mr. Smith himself, it was *veni, vidi et admirate.* He basked in the sun, at the foot of the orange trees and drank lemonade with Rufus Haines at Los Angeles. He was only two days behind a stage robbery on the road to Yosemite, and then he saw the Yosemite valley and would have left us without a glimpse of Shanghai and Canton, had it not been that an operator who was aware of Mr. Smith's wonderful power of concentrating ideas and producing results, almost forced him to see our miniature "flowery kingdom." He first visited that portion of which Beecher and Talmage gave such glowing descriptions. Thence through the retail portion of Hong Kong, drinking tea with Chong-Foo in the boudoir of Li Fong (or "The lady of the lake"), reclining on the sedan (extension sofa) of the once famous empress Li-yuen-pin and propitiating the pagan gods of fortune in the temple of Joss. Then he saw the tragedy of Tuni-mah-ka hi (The Black Thief and The Knight), enacted in the royal Li-hip-wo theatre—thence passed through many subterranean passages and "cologne alley," to the temple of Chinese statuary. Here, I might add, Mr. Smith for the first time manifested surprise—for he did not believe that the Chinese were so well advanced in sculpture; but when he saw the Venus of Hi-wah-mo, an artist, according to Dr. Li-po-tai, who so far surpassed all others of his time, and since—that his memory is canonized in the hearts of his countrymen—Mr. Smith stared in downright admiration and surprise.

It being Saturday night and as all places of amusement are closed by midnight, he determined to see the Chinese receiving and forwarding hospital. He was fortunate in finding in the receiving room an invalid who awoke as a light was struck in this dark chamber. By the aid of a taper he could see the patient was suffering from yit-ong, commonly called leprosy. That which you call "a rose by any other name would smell as sweet" Mr. Smith did not find it so—he had no fears of the yit-ong disease till the name was translated into the language of the "red devils" *leprosy*—Ah! It was then the finer nature of Mr. Smith arose in rebellion. He was prevailed upon to see the other chamber—a Chinaman had just died uncared for by living soul, none to close his eyes or repose his features, but left to stare in all the ghastliness of death—Mr. Smith could contain himself no longer; he said to one of his companions: "A Methodist minister in our town told me to be sure and see Chinatown. I have seen it, and I will never forget it. Steve Field has told me some stories, about it but I knew him to be an inventor, and hence thought his imagination might also be of an inventive turn in this regard, but that minister shall know now that I have seen Chinatown. I could forego the orange groves, the geysers, big trees, the wheat fields of San Joaquin, the vineyards of Senoma, the Cliff House, and all, but not Chinatown."

A company composed of some prominent gentlemen is being formed to run sewing machines by electricity on the Stockwell system, which is being now so successfully used in Philadelphia. This city offers a fine field for such a system, and it is being worked up by competent, energetic gentlemen whose names in connection with any electrical enterprise commands confidence and attention. It will be a boon to the women of San Francisco, and even to the coolie slave.

Nothing has been heard of late of Prof. Keith's electric railway although it was whispered that two experiments were not wholly satisfactory. Mr. Keith is sanguine, however, as is also Mr. Isaac Trumbo, his associate, who assured me that motors and dynamos were all ready and that the plan was entirely the idea of Mr. Keith, who proposed to take electricity from two wires laid between the rails. I have been assured a public exhibition would be given at an early day.

E. A. Beardslee is coming here ostensibly to work as an operator for the Western Union, but really to acquaint himself with the details to be ready to take hold when the time comes. Strange rumors are afloat, vague, but with a semblance of reality to back them up, that changes will take place, and changes that are to be deplored. Col. Clowry with his family, J. J. Dickey, C. H. Summers and a few notables are coming in a special car. Col. Clowry, it is said, with a pruning knife in hand.

SAN FRANCISCO, July 1, 1885.

ELECTRICAL NEWS AND NOTES.

TELEGRAPH LINES SEIZED WITHOUT NOTICE.

On Friday, July 10th, about 3 o'clock, General Eckert, representing the Western Union Telegraph Co., waited on General Farnsworth, receiver of the Bankers and Merchants' Telegraph Co., in this city, and presented an order from Judge Donohue, directing him to turn over all the property belonging to the American Rapid Telegraph Co. As is generally known, these lines had been leased to the Bankers and Merchants' company on the agreement that 6 per cent. yearly interest would be paid to the bondholders of the American Rapid company, and as the interest was not paid up, the stockholders became dissatisfied and accepted the proposition of the Western Union for a lease with similar terms. Gen. Farnsworth refused to turn over the wires until he had consulted with his attorneys to find out exactly what the property of the American Rapid company consisted of, and what belonged to the Bankers and Merchants' company, as the property of the two companies has been almost inextricably mixed up by running the wires of one over poles belonging to the other.

About half an hour after the order had been presented to him, Gen. Farnsworth was astonished to find that several wires were dangling in front of the building occupied by the Bankers and Merchants' company, at No. 187 Broadway. He found that Gen. Eckert had entered the building with a number of men, and had detached all the wires belonging to the American Rapid company on the cupola of the building, and also all owned by the Bankers and Merchants'. These wires were then being carried into the Western Union building, on the corner of Dey street and Broadway.

Mr. Lauterbach, of the firm of Lauterbach & Spingarn, attorneys for the Bankers and Merchants' company's bondholders, applied at once to Judge Donohue for a stay of proceedings. The application was granted, but not until the wires had all been taken into the Western Union building.

It would have been an utter impossibility for any Western Union employé to hastily select out of a hundred or more wires the exact ones which were the property of the American Rapid company, and no attempt was apparently made to do so, except, perhaps, under the general understanding that the only lines actually owned by the Bankers and Merchants' company were those leading south from this city and terminating at Washington. It appears, however, that there were wires of the latter company upon poles of the American Rapid, running through the state to Buffalo. No attempt was made to conceal the fact that the Bankers and Merchants' system was thoroughly crippled. On Saturday morning the public was so thoroughly informed of the shattered condition of the service, that little business would have been offered, even if it could have been transmitted. Under its harmonious relations with the Postal company, the transfer of such messages as were offered to accessible points was readily effected, but there were a number of wires leased to merchants and brokers, who were dependent upon them for the prompt transaction of their business. Such cases caused still greater annoyance, but no alternative was presented but to calmly await the process of law. About 30 eastern and 50 city wires were cut, 12 between Harrisburg and Pittsburg, also the wires at Buffalo, Rochester and Baltimore, under direction of the Western Union local managers at those points. The Bankers and Merchants' lines were carrying a large business at low rates, and it was evidently more the purpose to cripple the facilities of the company than to acquire them for the use of the Western Union. Not the least of the troubles was the probable loss of employment by perhaps 100 operators, although it was not deemed prudent to allow the force to become scattered until the question as to future operations was definitely settled.

The statements of Gen. Farnsworth and Edward S. Stokes—the latter a large bondholder of the bankrupt Bankers and Merchants' company—were to the effect that the linemen of the Western Union company gained access to the roof through an adjoining building. Mr. Stokes, who was found by a *World* reporter in a high state of indignation, said: "It is one of the most high-handed outrages that has ever been perpetrated upon the public, whose sympathies, I think, will be with us. It was a gross outrage when the Western Union company tampered with and manipulated the election returns in an endeavor to defeat Cleveland's election, but this last act of that corporation is even more atrocious, if that be possible. It was a deep-laid conspiracy," he added, "the parties to which you may guess from the facts which I will relate. And the strange part of it is that Judge Donohue, who issued the last order, was the very magistrate who, over the seal of the Supreme Court, issued the order for receivers' certificates, which were offered on the market, and of which I bought over $400,000 worth, paying cash, most of the property going into the possession of the company, whose possession he has now, without any notice to me, put into the hands of the Western Union.

"The way in which it was done is as follows," continued Mr. Stokes. "The Western Union ascertained last week that our reorganization committee was a success, and that three-fourths of the holders of $10,000,000 of our first mortgage bonds had agreed to the plan for protecting the property of the company, which was to sell the property and buy it in for the benefit of the bondholders, when a new company, the United Lines Telegraph Co., would be organized. This sale was to have taken place July 10th, and had been advertised for a month. A party, however, who would not give his name or tell who he represented—although we believe he acted for a man named Powers, who owns 200 of the bonds—made application to Judge Donohue to have the sale stopped. The bondholders, of course, opposed the application, offering to give a bond for ten times the amount in indemnity, but, much to their surprise, Judge Donohue granted an order postponing the sale. This he did Thursday, and he supplemented it Friday by granting this other order, when it is an utter impossibility for any one to separate the lines of the American Rapid and the Bankers and Merchants' without great study, as they are so intermingled.

"So interlaced were these lines that, as the Bankers and Merchants' had $2,000,000 invested in the American Rapid company, there was a suit pending to determine how the matter could be settled or compromised. Then, at almost the same time that Gen. Eckert presented the order to Receiver Farnsworth, a force of about 40 men in the employ of the Western Union, all armed with axes, get up on the roof of our building through the adjoining house, and, breaking the skylights, proceed to cut all the wire—American Rapid and Bankers and Merchants'—and to carry the cut wires into the Western Union building, so that it is impossible for us to repair the damage. Then, when our counsel goes before Judge Donohue, the latter admits that he may have acted hastily in the matter and made a mistake; that he regretted the inconvenience to which his order had put us, but that as the damage had been done, it was past all interference on his part, and that now it was a matter for litigation. That was a rather strange proceeding on the part of Judge Donohue, wasn't it, and also a strange admission for him to make after our wires had been cut in this manner and on his order?

"The Western Union now claims," concluded Mr. Stokes, "that this last move has effectually done away with all competing companies, and now they will not be troubled by any rivalry. That is the whole secret of the affair—it was done to frighten the people from putting any money into the telegraph business, as against the Western Union. It is impossible for us to estimate what loss this will cause us, for it will be impossible for us to repair the damage for months, unless we return like with like, and with an armed force enter the Western Union building and take out our wires. That we do not care to do."

Mr. Dwight Townsend, chairman of the Bankers and Merchants' Reorganization Committee, will call a meeting of the bondholders to be held as soon as possible, in order to consider the matter and lay the facts of the case before the grand jury, and he says that no expense will be spared to bring the perpetrators of this outrage to justice.

The penalty for illegal interference with telegraph wires is unusually severe, and during the troubles which have occasionally beset the Western Union company, its managers have freely threatened their adversaries with the terrors of the law, which is as follows:

> A person who wilfully or maliciously displaces, removes, injures or destroys a line of telegraph, or any part thereof, or any appurtenance or apparatus connected with the working of any magnetic or electric telegraph, or the sending or conveyance of messages by any such telegraph, is punishable by imprisonment for not more than two years.

Not only the person who commits the act, but also any one who orders or causes it to be done, is guilty of the crime, and may be punished. Section 29 of the Penal Code says:

> A person concerned in the commission of a crime, whether he directly commits the act constituting the offence or aids and abets in its commission, and whether present or absent, and a person who directly or indirectly counsels, commands, induces or procures another to commit a crime, is a principal.

The order granted by Judge Donohue on Friday, directing the transfer of the wires of the American Rapid Telegraph Co. to the Western Union, was made upon the motion of Dillon & Swayne, attorneys of the Western Union, upon a petition sworn to by Dr. Norvin Green, president of the Western Union. The motion was made in the suits brought against the Bankers and Merchants' company, of New York, New Jersey, Pennsylvania and Baltimore, by Austin G. Day, Alexander H. De Haven and the Farmers' Loan and Trust Co. The petition of the Western Union company stated that on July 1, Judge Shipman, of the United States Supreme Court, had made an order vacating an order previously granted, thereby permitting Edward Harland, receiver of the American Rapid company, to make such traffic arrangements or lease with other persons or corporations as he might consider to the best interests of the stockholders. It was in pursuance of that authority that Receiver Harland made a contract with the Western Union to manage the lines owned by the American Rapid company. The petition further stated that the

Digitized by Google

Bankers and Merchants' Telegraph Co. had no lease, contract or agreement entitling it or its receivers to the possession of the property of the Rapid company.

An affidavit of Frederick H. May, director of the American Rapid Telegraph Co., was attached to the Western Union's petition. Mr. May declared that the Bankers and Merchants' had no lease or contract entitling it to hold the property of the Rapid company.

Upon all occasions of this kind, Mr. W. B. Somerville appears to act as the official mouthpiece of the Western Union Telegraph Co. When others are reticent he is exceedingly loquacious, not only regarding the affairs of his employers, but of their competitors as well. In an interview upon the subject, he is reported as follows:

"The placing in our hands of the Rapid company's wires is merely what Mr. Edward Stokes and other stockholders of the Bankers and. Merchants' have been trying to do with their own property. They would have turned over to us at the same time the Rapid company's wires, but they are angry that they have not had their stock taken. The Baltimore and Ohio company has been trying to do the same thing for the past two weeks, and is still endeavoring to get us to take their wires. We took about 100 wires from the B. and M. building, but we have not as yet even made a schedule of them."

"Will you use the wires?"

"No, not until after July 14, at all events. The injunction granted by Judge Donohue last evening, and which was served upon Dr. Norvin Green by H. J. Schenck, the attorney for the Bankers and Merchants', prevents our doing anything with the property until the matter comes up before the court on Tuesday. We do not believe we have taken a single wire belonging to the Bankers and Merchants', as they claim, 'but should we have done so by mistake they can recover for any damages done.'"

The above statement in reference to the Baltimore and Ohio company drew out the following card from President Bates:—

To the Editor of the World:

The statement in Sunday's *World*, attributed to Mr. Somerville, of the Western Union company, that the Baltimore and Ohio company has been trying for the past two weeks and is still endeavoring to get us (the Western Union) to take their wires, is absolutely false. I have had no conference or communication with the Western Union company or any of its officers for months, and never at any time on the subject of a union with that company. The Baltimore and Ohio Telegraph Co. is controlled by the Baltimore and Ohio Railroad Co., and Mr. Robert Garrett, president of the latter, cabled me from London last Friday to deny the false statements. I sent a denial at once to the office of the New York Associated Press, but as the item did not appear in Saturday's New York Associated Press papers, I infer it was for some reason suppressed.

D. H. Bates,
President of the Baltimore and Ohio Telegraph Co.
West End, Long Branch, July 12.

The following is the substance of the statement presented before Judge Donohue by the counsel of the Bankers and Merchants' company, giving a general history of the growth of the system, and the damages sustained by the transfer of wires without proper notice:—

"The Rapid company's original system comprised a line of four wires from New York to Boston via Bridgeport, New Haven and Hartford. The poles were small and the wire inferior. Another line of four wires, by way of Hudson and Springfield, connected this city with Boston. From New York to Albany and Buffalo there was a line of six wires, and from thence to New Castle, Pa., an equal number most of the way. Four other wires connected New York with New Castle, via Philadelphia, Harrisburg and Pittsburg. Between New York and Philadelphia were three additional wires, thence to Baltimore six, and between there and Washington four. Baltimore was connected with Harrisburg by two wires. The farthest point west reached was Cleveland, and four wires connected that city with New Castle. All of the lines were built along the highway, and the Rapid's plant between New York and Philadelphia was of little account, as it ran through the trees and back yards.

"The Bankers and Merchants' original line comprised 22 wires to Philadelphia, 10 from there to Baltimore, and 8 thence to Washington. After amalgamation, the company added 14 wires on entirely new and substantial poles via Meriden, Hartford and Providence, to Boston. This was completed six or eight months after the amalgamation. Four extra wires were put up between Meriden and Hartford, and two from Meriden to Waterbury, Conn. The original four Rapid wires from Meriden to Boston were transferred from the old poles to the new pole line on account of the poor condition of those on which they were stretched. New London was connected with the system by a line of four wires from Willimantic, Conn. From the main line at Providence another of four wires was constructed to Newport via Fall River. On the poles supporting the six Rapid wires from New York to Albany and west to Buffalo, the Bankers and Merchants' added four new wires to Hudson, six from there to Albany, two to Utica, and four thence to Buffalo. They also placed on the Rapid poles from that city to New Castle four new wires. Between Philadelphia and New Castle six wires were added, and to Cleveland from that point six new ones were put up. Four wires were stretched from Baltimore to Harrisburg on the Rapid poles. The Western system was extended to Chicago from Cleveland, and a new and substantial pole line was erected bearing 10 wires. A very extensive and costly underground system, said to be the best in the world, was established in Chicago. No elevated lines are worked there, the wires being carried underground from 39th street to the main office in Madison street, near La Salle street, and to the branch offices. At the junction of the main line at Freeport, O., a branch with six wires was built to Toledo, and four from thence to Detroit. From Pittsburg a line of four wires was built west to Indianapolis via Cleveland, which closely follows the Panhandle railroad route. A branch of four wires from there to Cincinnati is just finishing. From Chicago to St. Louis the Bankers and Merchants' are in control by lease of the Board of Trade Telegraph Co., with three wires. Three additional wires were afterwards stretched on the same poles. They control two wires of the Pacific Mutual company from St. Louis to St. Joseph, Mo., via Kansas City.

"These lines are now cut off from the Eastern system. In almost all instances where new wires were put on, new instruments took the place of those in use by the Rapid company. New switch boards and furniture have been put in to accommodate the increased business.

"In this city messages were delayed by being transferred to other companies for transmission. The following private wires were also cut: Samuel Crump, to Montclair, N. J.; W. T. Hatch & Son, to New Haven; United Press Association, E. Sweet & Co., to Boston; L. Cahn & Co., to Boston; Charles Head & Co., to Boston; Seymour, Baker & Co., to Fall River, Mass.; *Inter-Ocean* Publishing Co., to Chicago and Washington; C. W. Brega & Co., to Chicago; Colbron, Chauncey & Co., to Boston; E. P. Schmidt, New York city wire; Chase & Higginson, to Boston; E. K. Willard & Co., to Boston; Taintor & Holt, to Boston; and Kidder, Peabody & Co., to Boston."

The following explanation of the action of the Western Union company was telegraphed to the superintendents and managers at all offices reached by the American Rapid Telegraph Co.'s wires:

The United States Circuit Court, in the suit of the trustee for the bondholders against the several American Rapid Telegraph companies, appointed Edward Harland receiver, and ordered that he take possession of the properties belonging to those companies, the Bankers and Merchants' company being also in the hands of a receiver under proceedings in the Supreme Court of New York, such receiver having or claiming possession of the American Rapid lines, although the order of appointment of the receiver of the Bankers and Merchants' company was limited to the property of the Bankers and Merchants', and did not extend to the property of the American Rapid company. A contract was made by which the Western Union Telegraph Co. is made the agent and attorney of Edward Harland, receiver of the American Rapid Telegraph Co., to take over and operate the lines. Therefore, application for possession was made to the Supreme Court, and an order granted directing the receiver of the Bankers and Merchants' company to turn over possession of the Western Union Telegraph Co., and authorizing the Western Union company to take possession of all the property of the American Rapid companies, and under that order most of said property has been taken possession of. On the night of the 10th inst., upon allegations of the receiver of the Bankers and Merchants' company, the Supreme Court made a further order directing that all further steps towards taking possession under the previous order be stayed until a hearing of both parties, set for the 14th inst., but not requiring any property in possession of the Western Union company, as agent of the American Rapid company, to be returned. (Signed), Norvin Green, President.

To offset this the Bankers and Merchants' representatives exhibit a written agreement, which they claim has been carried out by them in every particular, and that they owe nothing for the rental of wires. No notice has been served upon them by the American Rapid company that the latter desired to terminate the contract.

The agreement is signed by President A. W. Dimock for the Bankers and Merchants' company and by general manager G. S. Mott, of the American Rapid company, and is sealed and attested by J. G. Case, secretary of the former company. It is as follows:—

This agreement, made this 18th day of October, 1883, between the Bankers and Merchants' Telegraph Co., party of the first part, and the American Rapid Telegraph Co., party of the second part, witnesseth:—

(1) That each of the parties hereto gives unto the other the right to string wires upon any of the telegraph poles owned by it, and to use, maintain and operate such wires in the conduct of its business.

(2) Each company so placing wires on the poles of the other shall pay as a yearly rent $4 per mile of wire, such rent to be paid semi-annually, and if such rent shall not be paid, it is understood and agreed that said company may direct the other to remove said wires from its poles; and, if said wires are not so removed within six months after such notice, they shall become the property of the company upon whose poles they were placed.

(3) The right hereinbefore granted is expressly limited as follows:—

1. No wires shall be placed on any poles without the written consent of the company owning such poles first being obtained.

2. Such wires shall be strung under the wires then upon such poles, and shall be so strung, maintained and operated as not to interfere with the working of the wires of the company owning such poles, and each party hereto agrees to pay within twenty days after demand in writing made upon the superintendent of the district wherein any such injury may occur, the amount of any damage to the poles or wires of the company owning the poles upon which the other party heretofore may string wires, caused by the placing thereon of such wires and their necessary cross arms, under penalty of forfeiture of all right to keep and maintain its wires on the poles of the other party on the line where such injury shall have been sustained.

(4) Taxes assessed on polls and wires in all places shall be paid by the parties hereto ratably in proportion to the number of wires of each on the poles so assessed.

(5) Either party to this contract may after ten years from the date hereof terminate the right of the other to use its poles as herein described upon six months' written notice to the other, and if, after the expiration of the said six months such wires, with their cross arms, &c., shall not have been removed the

Digitized by Google

company owning the poles shall have the right to remove said wires, cross arms, &c., at the expense of the other party heretoor, at its option, to acquire and own the same after paying therefor $200 per mile per wire.

President D. H. Bates, of the Baltimore and Ohio company, is as well acquainted with the history of Western Union's methods of crushing out competition as any man in the country. Referring to the raid he said:—"The outrageous conduct of the Western Union in seizing by force the property of a rival company and then coolly saying to them, 'You have your remedy in the courts,' is only paralleled by the lawless deeds of this monopoly on a similar occasion.

"About ten years ago the Merchants' National Telegraph Co. had a line between Pittsburg and the oil regions of Pennsylvania. It was a short but important line, on account of its valuable connections with the cities and towns in the oil country. The property of the company was in the hands of the Western Union company, under a lease for ten years. Just before the lease expired, ten years ago, the Atlantic and Pacific Telegraph Co. bought a controlling interest in the stock of the Merchants' National, with the intention, of course, of adding its lines to their service. At that time the Atlantic and Pacific was competing with the monopoly company and was building up a good business.

"The Western Union seeing a valuable line about to pass out of its hands, resolved upon a desperate step. About a week before the lease expired, when that line would pass into the hands of the Atlantic and Pacific, the Western Union people, without even the shadow of a pretext in law, deliberately and secretly sent out 100 men to destroy the property of the Merchants' National company. About 75 miles of poles, wires and arms were dropped down and destroyed at different portions of the line, so as to wreck the entire property.

"Then the Western Union said to the Atlantic and Pacific, who owned the property, just as Dr. Green says now, 'You have your remedy in the courts.' Backed by the sharpest lawyers and with plenty of money, the Western Union knew that it was more than a match for its poorer and weaker competitor, and that they would be able to secure delay after delay before the case was tried until the Atlantic and Pacific people were tired out. This proved to be the case. The Atlantic and Pacific company could not fight the Western Union."

The daily press has been quite pronounced in its opinions of the raid. The following extracts will show the editorial views of different journals. The *Times* says:

The raid of the Western Union Telegraph Co. upon wires which did not belong to it was but another step in its struggle to maintain a monopoly over the telegraph system of this country. It was characterized by its usual methods of lawless disregard for the rights and interests of others and of the public, sustained by a sympathizing judge of the bench of the Supreme Court. The case is a plain one and no inside knowledge is needed for its perfect understanding.

* * * * * * * *

The plan was carried out in direct opposition to the interests and the wishes of nearly all those who had a stake in the property of the rival lines, and in utter disregard of the rights and interest of the public, because all the power and discretion of a judge of the Supreme Court was at the service of the monopoly. Anything like a judicial attitude or a desire to secure all the rights and equities involved would have suggested a more deliberate course, a full hearing in behalf of all concerned, and final action that would have had some regard for sound public policy as well as the rights of all parties to the controversy. But the end is not yet. Unless our judiciary is to be utterly discredited, steps will be taken to restore all parties to the legal position which they held before the forcible seizure of the wires was made, and lead to a fair determination of the rights of the bondholders of the two companies which the Western Union monopoly is trying to extinguish.

The *World*, under the head of "The Telegraph Anaconda," says:

There are two or three points in this last feat of deglutition which demand legal investigation, not only of a civil character but of a punitive character as well. Gen. Harland was appointed receiver of the American Rapid company by Judge Shipman. If he can be allowed to turn over his power as receiver to the Western Union company, that corporation was practically appointed receiver. Was it known to Judge Shipman that this was to be done when Harland was appointed?

Judge Donohue's extreme friendliness to Mr. Jay Gould's corporation needs explanation. Does Judge Donohue think it an honest judicial act to grant an order sufficiently broad to empower the Western Union corporation to seize not only the property of the Rapid but of the Bankers and Merchants' telegraph lines in the night time by the act of a band of marauders without giving the owners of the latter any notice?

It is time the people should be effectually protected against the telegraph anaconda. Its object in swallowing rival after rival is simply to rob the public by exacting high rates for telegraphic service. It had a double incentive now to seize the Bankers and Merchants' line by any high-handed outrage. If it can absorb every land line in the United States it will break down the "independent" or Mackay European Cable, which cannot long struggle on without land lines in the United States. And the Western Union and Anglo-American Cable company's interests are identical.

The *Herald* takes the ground that the raid was a violation of the law, as quoted above, and says:

The act of the Western Union in cutting and seizing the wires of the American Rapid and the Bankers and Merchants' was without warrant of law. The extraordinary ex-parte order of Judge Donohue did not give the color of legal authority for the depredation. That order directed Receiver Farnsworth to turn over the property of the American Rapid. The receiver said it was impracticable to obey it. The only lawful course then open to the Western Union was to go to the Court again. It had in Judge Donohue's order no authority or pretext to cut and seize the wires of the American Rapid by force against the protest of the receiver in possession, much less the lines of the Bankers and Merchants', whose transfer was not directed or contemplated by the order.

Besides being an offence against the criminal law, the act was a contempt of Court, punishable by imprisonment. A receiver is an officer of the Court which appoints him. He acts as the representative of the Court. He has been called "the hand of the Court." Property in his possession is in the custody and under the protection of the Court. Any unwarranted seizure of such property, any unlawful interference with it, is an offence against the Court. The Court is clothed with the power to punish the offender, and it is its duty to exercise that power. It is bound to do so to maintain its own authority, and the majesty of the law.

These principles are well settled and recognized. The United States Supreme Court thus gave expression to them in a recent case:—"A receiver is a representative of the Court. Property in his hands is in *custodia legis*. The Court will not permit his possession to be disturbed by force nor violence, to be offered to his person while in the discharge of his official duties. In such cases the Court will vindicate its authority and if need be will punish the offender by fine and imprisonment for contempt."

This power has been repeatedly exercised. It was exercised in the case of the recent strike on the Gould roads in Missouri.

The chaotic condition of the whole affair, caused by the numerous and conflicting interests involved, which are to be fought out in the courts, was a golden opportunity for the legal fraternity, and a most formidable array of lawyers appeared at the Supreme Court on July 14th.

Col. Robert G. Ingersoll appeared as counsel for the holders of the certificates issued by the receivers of the Bankers and Merchants' Telegraph Co., and asked for an adjournment of the hearing of the motions in the litigation to which the Bankers and Merchants' Telegraph Co. and its Receiver, Gen. Farnsworth; the American Rapid Telegraph Co. and its Receiver, Gen. Harland; the Western Union Telegraph Co., and the Farmer's Loan and Trust Co., as trustee of the ten-million dollar mortgage on the Bankers and Merchants' property are parties. The motions were, first, for the vacation of the order made by Judge Donohue on Friday directing the receiver of the Bankers and Merchants' to turn over to the Western Union, as the agent of Receiver Harland, all the property of the American Rapid company in his (Receiver Farnsworth's) possession under which Gen. Eckert, of the Western Union company, made his raid on the Bankers and Merchants' office and property; second, for the vacation of the injunction restraining the receiver of the Bankers and Merchants' from repossessing himself of the property taken from him by the Western Union people; third, for the opening of the decree obtained by the Farmers' Loan and Trust Co. on behalf of bondholders, foreclosing the ten-million dollar mortgage of the Bankers and Merchants' company; fourth, for the removal of the Farmers' Loan and Trust Co. from the position of trustee of that mortgage.

With Col. Ingersoll appeared Messrs. Edward Lauterbach, Charles Da Costa, Edward Guthrie, Francis L. Stetson, and Joseph Fettretch, as counsel for the parties directly interested in the Bankers and Merchants' company. Messrs. Turner and McClure represented the Farmers' Loan and Trust. The Western Union was represented by ex-judge John F. Dillon, Aaron J. Vanderpoel, and M. A. Eggleston. William G. Wilson championed the right of Receiver Harland to convey the American Rapid property to the Western Union, and Joseph Auerbach stood up for the bondholder, Powers, who objects to the foreclosure of the Bankers and Merchants' mortgage, and who desires the removal of the Farmers' Loan and Trust Co. from its trusteeship. It took a long time to have all these appearances noted, and to have it determined that all the motions should be heard at one time. Finally, Col. Ingersoll arose and informed Judge Donohue that he wished an adjournment. He said:

"The order made by Judge Shipman, of the United States Circuit Court, at Hartford, allowed his Receiver, Gen. Harland, to make such contract as he saw fit with any other person or corporation for the possession of the property of the American Rapid Telegraph Co. I have been informed that this court, acting under the order made by Judge Shipman—because that order was made—instructed its Receiver, Gen. Farnsworth, to deliver over to the agent (the Western Union) of that Receiver (Gen. Harland) the property of the American Rapid company; that afterward the agent proceeded to take possession of what they called the American Rapid company. There is, I believe a decree for the sale of the property of the Bankers and Merchants' company. The Western Union company, pretending to act under the order of Judge Shipman, not only took possession of the property of the American Rapid, but also of property of the Bankers and Merchants'—cut hundreds of wires belonging to the latter company, paid for with its money, strung on poles belonging to it—wires and poles never claimed by the American Rapid excepting through this agent. Now, the question arises, Would it be proper to sell the Bankers and Merchants' property under these conditions?"

"I entirely agree with you that it would not," said Judge Donohue.

"Would it be proper to sell this property, partly in the hands of enemies?"

"I have taken that to be so from the start," interjected Judge Donohue.

"Nobody would want to purchase a lawsuit at auction," continued the advocate. "You can get lawsuits at private sale. I move that these motions be adjourned unill Judge Shipman has had an opportunity of approving or disapproving of what has been done under color of his order. We say that his order has been violated, that an outrage has been committed, and that a certain wolf pretends to have an order from a shepherd."

No objection was made to an adjournment, although several of the counsel said they were ready to go on. In granting the

Digitized by Google

motion, Judge Donohue said he had put the Bankers and Merchants' company into the hands of receivers last September, appointing receivers who were selected not by him, but by the parties in interest. From time to time it had appeared to him that the company was run at a great loss daily, and it had been his impression that its affairs ought not to be kept open. But the parties in interest had chosen to keep them open, and he had not felt that, under the circumstances, he should interfere. And now his failure to interfere was made the source of strictures. He had been convinced that the decree of foreclosure protected nobody, but as everybody consented to its being entered he signed it. He suggested that the results of past slovenliness should be inquired into in the light of present criticism, and that, before the hearing of the motions, the neccessary amendments should be made to the decree. He then appointed July 21 as the adjourned return day, and ordered all proceedings to be stayed meanwhile.

On July 16th the United States Court at Hartford, Conn., became the centre of interest in connection with the difficulties. Arguments were heard on a motion in the interests of the Bankers and Merchants' Telegraph Co., for an order to regain possession of its own lines, or wires strung on the poles of the American Rapid company, until the question of approving the contract made by Receiver Harland with the Western Union company shall be finally acted upon. An affidavit of F. W. Jones, general manager of the Bankers and Merchants' company showed that the wires claimed exclusively by the Bankers and Merchants' company could be readily identified. It was contended by counsel for the company that a contract was made by it with the Rapid Telegraph company in October, 1883, under which its property was kept distinct. By this agreement each company was to pay the other a given sum per mile of wire for the use of wire and poles owned by each.

Ex-Judge Dillon, counsel for the Western Union, said he was ignorant of the existence of any such contract and that it was not on record, but Mr. Ingersoll showed that it had been read at a former hearing. The latter's closing argument for the Bankers and Merchants' was to the effect that nothing unfair was asked, but only this—that the Bankers and Merchants' might have the use of its own property until judicial proceedings deprived it of it: that this use would not deprive the Western Union of any of its rights nor interfere with the use of the wires of the Rapid company. He said the court could not afford to permit, under the sanction of its own authority, such a violent construction of the contract entered into by its receiver as the use of an axe to cut wires on the very day the contract was entered into between the receiver and the Western Union company.

Judge Shipman at the close of the arguments spoke in support of the receiver's acts as being open and above board. It must be admitted, he said, that the allegation that the wires of the Bankers and Merchants' could be identified has been made for the first time to-day. It was impossible for him to determine by affidavits presented by one side only whether the wires designated were the property of the Bankers and Merchants' or not. The location of the wires has hitherto been unknown and indistinct to the receiver. It was right, he thought, that pending the action of the Court upon the contract the wires in dispute should be in the use and control of the Bankers and Merchants'. This is a side issue, which ought to be taken out of the main issue, and he would order that the receiver should be tendered the use of these wires subject to the order of the Court upon the confirmation of the contract with the Western Union.

The Court held a session during the evening, expecting that counsel would be able to agree upon the form of order to be issued. But an agreement was not reached, though the differences, relating mainly to descriptions of property, were slight.

Judge Shipman had previously announced his disqualification to try the main question as to the approval of the contract made by the receiver with the Western Union company. He is a small shareholder in the American Telegraph and Cable Co., which is leased by the Western Union, and he holds the relation to be that of landlord and tenant, as defined by Connecticut laws, and while there is no Federal statute to interfere, and the state law is not obligatory upon him, yet he says that the latter should be respected and that he is morally bound by it.

The following day he signed the order for the restoration of the telegraph lines claimed by the Bankers and Merchants' to that company. Gen. Harland, receiver of the American Rapid Telegraph Co., the Western Union company and the officers, agents, attorneys and employés of the same are instructed to see that this is done. Furthermore they are directed not to interfere with or hinder the operation, use and enjoyment of the lines.

The property held by the Western Union which is ordered to be returned to the Bankers and Merchants' is divided into three classes: 1, Bankers and Merchants' wires on Rapid poles; 2, Bankers and Merchants' poles on which Rapid wires are also strung; 3, Bankers and Merchants' wires on Rapid poles in New York city.

Under the order of Judge Shipman, the Western Union Telegraph Co., as the agent of the Rapid company, July 18, began turning back to the Bankers and Merchant's company such wires as the order called for. The wires are situated between Cleveland and Boston, and aggregate 6,000 miles in all, and are all on the poles of the American Rapid company, with the exception of a few hundred miles.

Under the order the Bankers and Merchants' company is required to turn over to the Western Union company all the wires of the American Rapid company now in its possession between Cleveland and Chicago and from Pittsburg to Indianapolis, via Cincinnati, and the loops to the oil centres, in all 6,150 miles, being about the same mileage as turned back to the Bankers and Merchants' in the East. This, the Western Union says in effect, cuts off the Bankers and Merchants' company from any connection west of Cleveland on the northern circuits and west of Cincinnati on the southern, and from connection with most of the oil cities.

In addition the Bankers and Merchants' is required to turn over all the instruments, switches, offices, tables, &c., in its possession belonging to the American Rapid company. The Rapid company claims that while the mileage of wire to be turned over to each company by the order is about equal that to be turned over to it in the East, it is by far the most valuable for business purposes, and includes 700 miles of poles.

Judge Donohue in Supreme Court, Chambers, New York on July 24, denied the motions to set aside the decree of foreclosure in the suit of the Farmers' Loan and Trust Co. for the forecloseure of the $10,000,000 mortgage upon the property of the latter company, in which a decree was entered authorizing the sale of the property, and for the removal of the Trust company from its position as trustee of the mortgage. The decree in the foreclosure suit was entered upon consent of all parties to it. Judge Donohue says that there are many defects in the decree, and the specific property sought to be covered by it, he says, can nowhere be found in the decree. Therefore, when the referee comes to sell the property, it will be somewhat difficult to tell what he sells and where he gets the power to sell any definite property. But the Court agrees with the Trust company that the applicant who represents $250,000 of bonds has no right at this time to intervene as a party to the suit, and for that reason the motion must be denied. He disagrees, however, upon the point that the objections are matters addressing themselves to the purchaser. He says:

> In my judgment this goes to the title of the property, and all dealings with it take with it full notice of the defects, and it seems to me buy with it, as one of the counsel for the bondholders remarked "a crop of lawsuits;" but on this application of the moving party I cannot interfere. On the motion for removal, I do not consider the merits at all, as a large mass of the bondholders now appearing are satisfied with the trustee. The Court fully agrees with the plaintiff on the propriety of an early sale, and pointed out the necessity long since of such a course, but I do not agree with them on either the necessity or propriety of what may be selling what may prove a defective title.

THE BALTIMORE AND OHIO COMPANY BURNED OUT.

At 7:40 P. M. July 4th, smoke was seen to issue from the basement of the building 63 Broadway. Policeman Wm. Clark sent out an alarm from the corner of Rector street.

Engine Company No. 6 was the first to appear on the scene, and as the men pulled up at Trinity place and Rector street flames were pouring out of the rear, and a second alarm was sent out. The blaze then broke out of the windows of the operating room on the Broadway side, and as it was known that there were a number of operators in the room much uneasiness was felt as to their safety. But when the firemen got up there they found the rooms deserted. When the smoke first reached the top of the building there were about twenty operators in the room. The fire increased so suddenly, and the volumes of smoke became so dense that they were afraid to attempt to gain the street by the stairs. A ladder which runs to the cupola, where the wires enter, enabled them to reach the roof. They then reached the street through the American Express Company's building, which adjoins. They had hardly left their places when the room was in flames.

A third alarm was sent out, and shortly afterward special alarms summoned four more engines. On the Broadway side the flames poured fiercely out of the fifth story windows. The offices of the American Express Company adjoining on the north, and those of the Adams Express Company on the south, seemed to be in peril. The breeze from the south caused the fire to lick both these buildings, but a strong stream was soon playing from the water tower and they were saved. After this there were two loud reports as if caused by explosions, and the flames gained new strength. But the stream from the water tower was well directed, and the flames began to dwindle. In the meantime the rear of the basement at No. 45 Trinity place was in flames, and the fire made rapid progress up the elevator. Another call was immediately sent out, but the combined forces were unable to subdue the fire until the immense stock of vitriol and telegraph instruments belonging to the Baltimore and Ohio company had been destroyed. On the ground floor was also a large stock of hides and vanilla beans, which were entirely destroyed.

Digitized by Google

The fire burned rapidly on the Trinity place side of the building, and soon the whole structure was in flames, and long, fierce tongues of fire shot out into the street. Owing to the fact that the elevated road runs close to the buildings, the firemen were handicapped in their endeavors to successfully reach the upper windows, and it was only by working at one floor at a time that any results were accomplished. The hose was hauled up on the elevated tracks, and travel was delayed thereon for over two hours.

By desperate fighting the fire was confined to the basement, first floor and top story. When under partial control several firemen crawled along the cornice, which had been badly eaten out by the flames, and turned on a stream of water, but it was not until after two hours' hard fighting that all danger of the spreading had passed. Even towards the last the fire would regain new life and become dangerous.

The basement is used by the telegraph company for its messenger department and as a store-room. The fire originated in the rear.

In the basement were stored the battery supplies, and there was also a small restaurant, and a wardrobe containing messengers' uniforms.

Several boys who were on duty say that there were several firecrackers exploded during the day. One was heard to go off in the dark room, which was used for storing paper. So it is supposed that the boys let the cracker fall among the paper, and the fire probably slumbered for some time before breaking out.

Temporary quarters were secured for the operating room at 61 Broadway, the aerial cables led in, new supplies of instruments and battery secured, and on Monday morning facilities had been provided for the transmission of all business.

The loss to the telegraph company was about $10,000 on which there was no insurance. The executive offices are now located at 57 Broadway.

DECISION IN BURGLAR ALARM SUIT.

HOLMES ELECTRIC PROTECTIVE CO. *v.* METROPOLITAN BURGLAR ALARM CO.

U. S. Circuit Court, Southern District of New York.

Decided December 4, 1884.

1. It is only a patent for an invention that has been previously actually *patented* in a foreign country that is limited by the foreign patent.
2. The mere *description* of an invention in a foreign patent does not operate, under section 4887 of the Revised Statutes, to limit a domestic patent for such invention.

STATEMENT OF THE CASE.

This suit was brought for an infringement of Letters Patent No 120,874, granted Edwin Holmes and H. C. Roome, November 14, 1871. An injunction was granted, after argument, September 2, 1884. On November 22, 1884, the suit came up on motion of defendant to vacate the injunction. The ground of this motion was that the invention had been previously patented by the inventors in an English patent dated November 1, 1870, the 14 years' term of which expired November 1, 1884, and that by consequence the patent in suit expired at the same time.

Complainants opposed the motion on the ground that while the invention was *described* in the specification of the English patent, it was not "patented" therein within the meaning of section 25 of the Patent Act of 1870 or section 4887 of the Revised Statutes, the *claims* of the English patent not being for the invention set forth in the claims of the patent in suit and incidentally described in the specification of the English patent.

Mr. S. A. Duncan for the complainant.

Mr. F. W. Whitridge for the defendant.

WHEELER, *J.:*

The invention patented in the patent in suit, as the same was construed in granting the injunction now sought to be dissolved, was not patented in the English patent which has expired, the expiration of which is relied upon to terminate this patent, and is the ground of this motion.

It is only a patent for an invention that has been previously actually patented in a foreign country that is limited by the foreign patent. The description of the invention in the foreign patent might affect the validity of the domestic one, and might not, but would not limit it. (Rev. Stat., sec. 4887.)

The effect of the various patents was considered when the injunction was granted as bearing upon the validity and construction of this one, and those questions are not open upon this motion as made.

The motion is denied.

HEAVY JUDGMENT AGAINST THE WESTERN UNION.

Upon the report of Referee James C. Spencer, a judgment was entered, July 24, in the Superior Court against the Western Union Telegraph Co. and in favor of James H. Goodsell for $240,159.11. In January 1881, Mr. Goodsell, as president of the National Associated Press, made a contract with the Atlantic and Pacific Telegraph Co. for the dissemination of news. The contract went into effect on Feb. 1, 1881, but on Feb. 3 the Atlantic and Pacific company fell into the hands of the Western Union company, which assumed to carry out its contracts. The Western Union company in 1882 charged Mr. Goodsell greater rates, and stopped the service because he refused to pay them. In July, 1882, Mr. Goodsell brought suit against the Western Union company to recover $22-000, which, he alleged, the company had collected from different newspapers for his service and had failed to account to him for. He also asked for damages to the extent of $650,000 for a breach of contract. The Western Union company alleged that the contract was invalid and fraudulent, and that a new arrangement had been made and carried out, but that finally Mr. Goodsell abandoned the work. For this they put in a counter claim for $15,000 damages.

Of the judgment entered on the referee's report $220,306 is for damages and $16,777.42 for money due, the rest being interest.

OFFICIAL ETIQUETTE OF THE ASSOCIATED PRESS.

It is so rarely that the public is given an insight into the peculiar methods of the Associated Press that the following telegram should be of interest:

CHICAGO, July 15, 1885.

To D. H. BATES, *President of the Baltimore and Ohio Telegraph Co., New York:—*

In the New York papers of Monday which have reached here I find your card relative to the statement that the Baltimore and Ohio company had been trying to get the Western Union Telegraph Co. to take its wires. I regret that you made the reference you did to the Associated Press without first inquiring into the facts. As you have always had courteous treatment at our hands and have secured through the Associated Press publicity for your business on various occasions, this insinuation of suppression is ungenerous. There is an unwritten law in the office which forbids the denying of statements of that character unless made by some agent of the Associated Press. This law is to prevent unpleasant complications with the individual newspapers. The day manager of the New York office informs me that as your letter accused the *Post* of publishing a falsehood, he was restrained by the rule from giving out your letter to the New York papers. He did, however, supply the fact of denial to outside papers. If you had sent to us a general statement not involving a question with an individual newspaper it would have received just such attention as you wished in this case. This suggestion applies to the future as well as to this single instance.

You know that the Associated Press has no relations with the Western Union Telegraph Co. that stand in the way of extending to the Baltimore and Ohio company any courtesy or any business we choose. Hence we have no interest in suppressing anything that you wish to make public coming within our rules applicable to all. Let me hope that hereafter you will avoid any public statement conveying a different impression.

WILLIAM HENRY SMITH, General Manager.

ORGANIZING THE UNDERGROUND COMMISSION.

The underground wire commission, appointed under the laws of 1885, to compel the telegraph, telephone, and electric light companies to take down their poles and place their wires underground, held its first meeting for organization at the Metropolitan hotel, July 20. Mr. Hess called the meeting to order, and nominated for president Mr. Loew, who was unanimously elected. Mr. Moss was appointed secretary, and F. A. Lovcraft assistant secretary.

The commission having thus organized for business, president Loew offered a long preamble and resolution, declaring that under the law it was the duty of the commission to cause all telegraphic, telephonic and electric light wires to be put underground, and that the commission proposed to do the work for which it was appointed as speedily as possible. The law requires that plans and maps, with estimates of cost, shall be filed by the companies with the board within 60 days after its passage, or before Aug. 14, and if they do not do this the commission is authorized to adopt a plan of their own. It is the purpose of this board, the preamble says, to cause the wires to be placed underground, and the secretary is instructed to notify all persons or companies owning or controlling the wires above ground that the board will receive at the Metropolitan Hotel any plans, maps, or methods proposed for its approval; and that it requests that such plans be submitted as soon as practicable before the expiration of the 60 days prescribed in the law. The resolution was passed The following, proposed by Mr. Hess, was adopted.

Resolved, That the owners, lessees or occupants of houses be requested to refuse permission for the placing of any telegraphic, telephonic, or electric wires over or on their respective buildings, without first securing a permit from this board.

Another resolution, offered by Mr. Hess, requesting the companies to offer to the board at its next meeting any plans which they may have for placing new wires above ground, was passed, and the commission adjourned.

Mr. Moss said to a reporter, in reference to the work to be done: "We are thoroughly in earnest and intend to see that the Daly bill is executed. We don't believe in oppressing the companies, of course, but we shall do our whole duty under the law. The poles and wires must go, and if the companies do not present plans to us before Aug. 14 we shall certainly adopt a plan of our own and see that the wires are buried in accordance with it. The companies will have to spend some money at first, of course, but I believe in the end it will be money in their pockets. The commission, at all events, is thoroughly in earnest, and will do the work intrusted to it faithfully."

BOSTON ELECTRIC LIGHT COMPANIES CONSOLIDATE.

After a year's negotiations the three electric light companies of Boston have determined upon combining their forces. They are the Brush Electric Co., the New England Weston Electric Co. and the Merchants' Electric Light and Power Co. The new combination will be known as the Union Electric Light and Power Co. of Boston, and is to be organized under the general laws of Massachusetts, with a capital stock of $700,000, the par value of the shares to be $100. The stock will be divided as follows : Brush company, $250,000; Merchants', $225,000, and Weston, $225,000. It is estimated that the plant of the three companies has cost $1,000,000. The Brush company has a debt of $91,000 and the Merchants' a debt of $47,000, while the Weston company is free from liabilities. The consolidated company will assume these debts and put the same in 15 year bonds. It is estimated that the real estate acquired by the combination will offset the debts.

THE STANDARD UNDERGROUND CABLE COMPANY.

The vast extent of the electrical systems in New York and Brooklyn, which are to be placed underground "wherever practicable," renders this an important field for the introduction of approved subterranean methods. To meet the anticipated demand, the Standard Underground Cable Co. has established at 128 Pearl street, in this city, an agency for the sale of the Waring lead-covered cables. Mr. George L. Wiley has assumed the management of the New York office. Mr. Wiley is thoroughly versed in the requirements of the electrical companies for city work. With fourteen years experience in the private line and telephone service as operator, chief operator, assistant superintendent, and superintendent with the Gold and Stock Telegraph Co., and Metropolitan Telephone and Telegraph Co., he will be found a competent adviser to all who propose to avail themselves of the advantages of the system which he now represents.

THE PITTSBURG TELEPHONE DECISION.

The Western Pennsylvania Telephone and Telegraph Co., about a year ago, entered into the telephone business at Pittsburg, Pa., as a licensee of the National Improved Telephone Co., of Louisiana, using instruments said to be based on the patents of C. A. Randall and J. Harris Rogers. An exchange system was built up, embracing over 300 subscribers. Suit was brought against the company by the American Bell Telephone and the Central District and Printing Telegraph companies for infringing the Bell patents. The defense was based mainly upon the anticipation of the Bell telephone by the Reis transmitter. The hearing was before Judge McKennan and District Judge Acteson. Counsel for the defense had barely started his argument, when he was stopped by Judge McKennan, who ordered a preliminary injunction. The business of the company is now at a standstill, and the instruments of the subscribers are being removed. No new points whatever were developed by the litigation.

THE USES OF PHOSPHOR-BRONZE.

The new catalogue issued by the Phosphor-bronze Smelting Co. of Philadelphia, will be found of interest to all who desire to know of the advantages possessed by this beautiful metal, for various mechanical purposes. For special electrical use it is manufactured into line-wire ranging from number 6 to 20, both bare and insulated ; cast-rods and wood-screws are also furnished for shop work.

TELEPHONIC LITIGATION IN CANADA.

In the case of the Bell Telephone Co. *vs.* Telephone Manufacturing Co., an action brought to cancel the Bell patent for not complying with certain regulations of the patent law, the Bell company last May made application for a writ of *certiorari* to remove all proceedings, evidence and papers from the Department of Agriculture into the Common Pleas Division, contending that the Minister of Agriculture had no authority to adjudicate upon the validity of the patent so attacked. A full court, on June 27th, decided otherwise, and dismissed the Bell motion with costs.

TABLE OF RESISTANCES OF PURE COPPER WIRE.

We have reprinted in our advertising pages this issue the valuable table of resistances calculated by George B. Prescott, Jr., which appeared in our June number. This will enable our readers to cut it out, without mutilating the magazine for binding. The copyright of this table has been assigned to Messrs. Holmes, Booth & Haydens, and its future publication has consequently passed into their hands.

ELECTRIC LIGHT AND POWER.

Domestic.

One hundred feet of the Hoosac tunnel will be arched with brick this summer, instead of 50, as in former years. The problem of lighting the tunnel has not been satisfactorily solved. It is said that electric lights are hardly practical, as they will not penetrate the smoke. Manager Locke thinks smoke-consuming engines will some time be constructed to pass through the tunnel, when it will be an easy matter to keep the tunnel sufficiently lighted.

The electric light-carriage, or "telpherage" system, is being experimented with in Philadelphia. Two cables are used, one above the other, the packages being suspended from the upper and steadied by the lower, and the cables serving as conductors.

The company recently organized at Westchester, Pa., for the purpose of furnishing electric light in the borough, have closed a contract for a plant of the Edison incandescent system, and the work of preparing a building for housing the same has been commenced. Some arc system for street lights will soon be settled upon by the same company, which has a capital of $30,000.

The Electric Railway and Power Co. have filed articles of association with the Secretary of State in Missouri; capital, $350,000. The company's board of directors is composed of the following named citizens of St. Louis: John W. Harrison, John Jackson, B. D. Lee, John N. Bofinger, Aug. Gehner, John W. Donaldson, Chas. Hoyle, T. S. McPheeters, R. D. Lancaster, Francis E. Nipher, Wellington Adams, Chas. Thaw, Edwin Harrison.

Eight electric arc lights have been placed in the Union baseball park, St. Louis, to enable athletic sports to be carried on at night.

The city council at Kansas City, Mo., has awarded the Local Electric Light Co. a contract for furnishing them with 25 Thomson-Houston arc lights. If these are satisfactory, the number will probably be increased.

The Bain Electric Co. of Chicago, are putting a plant of electric arc lights in the Bates House at Indianapolis, Ind., and a plant of incandescent lights at Menasha, Wis.

The Reading, Pa., Electric Light Co. have made arrangements by which they can furnish from one to 100-light dynamos to persons who may want to run their own lamps.

Foreign.

During the past six years dynamos to the number of 6,000 have been constructed in the different workshops in Germany, representing a value of $3,500,000. The number of arc lamps made during the same period was 20,000, realizing $1,250,000.

Six British gunboats are to be supplied immediately with dynamo-electric machines and engines for working the electric light, and every effort is to be made to bring the equipment up to the most advanced stage of the art of electric naval illumination.

Consul Stevens writes from Victoria, B. C., that the electric light and telephone systems prevail, but the city has no sewerage, and the sidewalks are of wood.

An electric railway is about to be constructed between the village of Saint-Maurice and Pontresina. The motive power will be derived from the waterfall of L'Inn, which will also be utilized to supply the force necessary in the electric lighting of the village. It has been specially stipulated that the new railway shall not in the slightest degree detract from the beauty of the neighborhood.

Mr. Reckenzaun has produced designs for a torpedo-service launch, to be propelled at high speed by electricity. The conditions enjoined are that this craft should make a voyage across the English Channel and back in moderately fair weather. It is confidently believed that the test can be complied with, and the construction of the vessel and machinery is to be commenced without delay. In view of important improvements in the electrical appliances her speed may be expected to exceed anything hitherto attempted.

MANUFACTURING AND TRADE NOTES.

The cable manufacturing business established by Samuel C. Bishop, and for many years known as the Bishop Gutta-percha Works, has been transferred to the newly formed Bishop Gutta-percha Co., of which Samuel Boardman is agent. Mr. W. W. Marks will still continue the superintendent. This is the only establishment in the country devoted to the manufacture of gutta-percha insulated wire and cables.

The Brown Electric Co. are preparing to occupy their new quarters, 1, 3 and 5 Michigan street, Chicago. In these works they are putting some very fine machinery. They are also fitting up a laboratory with complete appliances.

The Western Electric Co. at Chicago, has recently put into operation at Mansfield, O., an electric light plant, and has placed

Digitized by Google

50 lights in Dickinson's bazaar, St. Paul, Minn. It is turning out large quantities of cable and sending to the Bell Telephone Co. at Pittsburg 195 miles of conductors, An order for five miles of conductors has been sent to Washington, D. C. The company is making a multiple switch-board for shipment to Antwerp, Belgium.

MISCELLANEOUS.

The Electric Protection Co. has been organized in Philadelphia with a capital of $50,000. The officers are as follows: President, Charles M. Swain; secretary, Wm. Carley; treasurer, Geo. B. Dresher; directors, Chas. M. Swain, Chas. D. Freeman, Wm. P. Wheatland, R. Lloyd Lee and Harrison Stiles.

The Electric Aurophone Co. has recently been incorporated in St. Louis, with a paid up capital of $50,000, for the manufacture and sale of Ehrlich's electrical device for the improvement of hearing. The officers are: J. A. Parker, C. C. Nicholls, and E. V. M. Powell, president, vice-president and secretary, respectively.

The Secretary of State of Illinois has licensed the American Burglar and Fire Alarm Co.; capital stock, $30,000; incorporators: Robert Wiseman, Charles W. McClellan, and D. L. Foote.

PERSONAL MENTION.

Charles Williams, Jr., one of the oldest electrical instrument manufacturers in the country, is about to retire from business. The Boston factory, which has been devoted to the manufacture of telephones for the past six or seven years, is to be closed and the work transferred to the New York and Chicago factories of the Western Electric Co. Mr. Williams was among the early and fortunate pioneers in the telephone industry, and is believed to be well prepared to enjoy his release from the care and responsibility necessarily attendant upon the management of a large manufacturing establishment.

Henry W. Pope and wife sailed for Europe, July 16th, on the steamer *State of Alabama*, for a two months' trip. They arrived safely at Glasgow on the 27th ult., after a pleasant passage.

THE TELEGRAPH.

A Texas paper reports that the corn-stalks in that state are so tall and large that they are being used as telegraph poles by the Baltimore and Ohio company.

The Pennsylvania Railroad Co. has introduced a new and very accommodating feature on the limited trains. The conductor on each of these trains is supplied with a large package of envelopes, each of which is weighted with lead, so that they may be tossed from a moving train to the station agent by passengers who wish to forward telegrams before the train reaches its next stopping place. On the envelope are printed directions for the telegraph operator to forward the despatch at once.

In the case of the city of New Orleans against the Western Union Telegraph Co. to recover $3,060 on an ordinance which provides that no telegraph poles shall be allowed to be erected in certain portions of the city except upon payment of $5 per annum for each pole, a decision has been rendered in the United States Court allowing judgment to the full amount against the telegraph company.

The Empire and Bay States Telegraph Co. has been incorporated by a certificate filed in the New York County Clerk's office. Its capital is $250,000, but may be increased to $10,000,000. Its lines are to run from this city to the east and south and along the Atlantic coast generally. The incorporators of the company are Andrew J. Baldwin, John Henry Miller, and Charles J. Marsh. The first named two hold 1,000 shares each, and Mr. Marsh 500.

The Atlantic Telegraph Co., incorporated under the Maine and New Hampshire laws, with a capital of $100,000, has been organized. The new company, which is owned by Boston and New York capitalists, will not extend its wires beyond New England. While it has been started purely as a local institution, an important alliance has been entered upon with the Baltimore and Ohio company. The officers are as follows: president, John W. Deering; treasurer, John J. Donovan; superintendent, Edward A. Leslie.

At a meeting of the incorporators of the Pacific Telegraph Co., held in Wyandotte, Kas., the following officers were chosen: E. L. Martin, of Kansas City, president and treasurer; E. S. Stokes, of New York, vice-president; George M. Meyers, of Kansas City, secretary; L. D. Parker, of Chicago, auditor. The capital stock of the company is $300,000. The majority of the stock has been subscribed in Kansas City and Omaha.

THE TELEPHONE.

The telephone subscribers of Evansville, Ind., in convention assembled, have resolved to pay no more than $3 per month for their telephones. The Indianapolis subscribers had previously made a similar decision.

Suit was entered in the United States Court at Memphis on the 10th inst., by the Pan Electric Telephone Co. against the American Bell Telephone Co. The bill filed charges that the Bell company's patents interfere with the Pan Electric patents, and are, to that extent, void; that the Bell company has slandered and misrepresented the patents and inventions of its opponents; that the Bell telephone in use is not the one described in its original patent, which is used only to litigate with; that Bell was not the first and original inventor of the art, it being known to, and described by Philipp Reis, of Germany, who died in 1874.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER *by* Pope & Edgecomb, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From June 16th, to June 30th, 1885 (inclusive).

Alarms and Signals:—*Transmitter*, J. C. Wilson, 320,032, June 16. *Push-button*, John Geary, 320,238. *Burglar Alarm*, A. Jacobi, 320,660, June 23. *Bell*, H. B. Porter, 320,685. *Call Instrument*, F. B. Wood, 321,073, June 30. *Method of Producing Responding Signals*, A. G. Holcombe. 321,110.

Clocks:—F. Bauman, 320,997, June 30.

Commutators:—*Switch*, E. C. Titus, 320,019, June 16. *Circuit-breaker*, E. Weston, 320,028. *Circuit-closer*, J. E. Root, 320,504, June 23.

Conductors, Insulators, Supports and Systems:—*Conduit*, Charles G. Perkins, 319,998, June 16. *Cable*, P. B. Delany, 320,229. *Conduit and Discharger*, E. H. Hoffman, 320,253. *Conductor*, Leo Daft, 320,632, June 23. *Insulating Pipe Union*, C. H. Fischer, 320,645. *Method of Making Conductors*, W. S. Platt, 320,684. *Insulating Compound*, R. S. Ferguson, W. Schumacher and W. Tubman, 320,921. June 30. *Joint for Cables*, W. R. Patterson, 321,240. *Means for Driving Conductors into Conduits*, D. N. Hurlbut, 321,363.

Dynamo Machines and Motors:—*Engine*, C. A. Jackson, 320,137, June 16. *Core for Armatures of Dynamos*, J. H. Muller, 320,158. *Dynamo*, J. M. Rivera, 320,170. *Regulator for*, M. G. Farmer, 320,234. C. L. Buckingham, 320,840, 320,842, June 23. *Armature for*, A. H. Bowman, 320,754. *Reciprocating Engine*, C. J. Van Depoele, 320,515. *Motor*, J. M. Pendleton, 321,049, June 30, Frank J. Sprague, 321,147, 321,148, 321,150.

Electrolysis.—*Process of Depositing Nickel*, J. G. Mathieu, 320,577, June 16.

Galvanic Battery:—Otto Fleming, 320,547, June 23.

Ignition:—*Gas Lighter*, C. A. Hussey, 320,065, June 16. *Turning on, lighting, and shutting off Gas*, L. S White, 320,105, 320,106. *Gas Lighter*, same, 320,-606, June 23. *Igniter for Gas-Engines*, D. S. Regan, 320,285, June 16.

Lamps and Appurtenances:—*Arc lamp*, E. Thompson, 320,018, June 16. G. Pfannuche, 320,585, June 23. C. L. Buckingham, 320,841, 320,848. *Holder for Incandescent Lamp*, E. Weston, 320,026. 320,027, 320,029, 320,030, June 16. *Socket and Switch*, D H. Cunningham, 320,117. *Manufacture of Filaments*, F. Schaefer. 320,297. *Incandescent Lamp*, John A. Yunck and John Stuertz, 320,739, June 23. *Moulds for making Incandescents*, O. A. Moses, 321,309, June 30.

Measurement:—*Rheostat*, J. Doyle, 321,285, June 30.

Miscellaneous:—*Device for Preventing False Alarms*, 320,068, June 16. *Sight for Fire-arms*, W. Winans, 320,200. *Process for Setting Type*, J. E. Munson, 320,271. *Type-setting Machine*, same, 320,272. *Device to Enable Showmen to Walk on Ceiling*, N. H. Clyde and W. Berrigan, 320,275. *Machine for Dressing Carbons*, W. J. Possons, 320,497. June 23. *Game Indicator for Pool-tables*, 320,542. *Lock*, C. Blattmann, 320,617. *Induction Coil*, W. Stanley Jr., 320,717. *Mariner's Compass*. R. L. Sleater, 320,823. *Mechanical Movement*, S. Tideman, 321,062, June 30. *Registering Apparatus*, 321,069. *Exercising Machine*, G. P. Clark and G. Harsin, 321,278. *Combined Weighing Scale, Flour and Bran Packer*, C. W. Roth, 321,387.

Protectors:—*Cut-out for Circuits*, E. Thomson and E. W. Rice, 320,017, June 16. *Protector for Instruments*, D. J. Cartwright, 320,912, June 30, W. F. C. M. McCarty, 321,235.

Railways and Appliances:—*Tramway*, C. Basto, 319,947, June 16. *Locomotive*, J. Weis, 320,025. *Car*, A. Reckenzaun, 320,092. *Railway System*, F. L. Pope, 320,283. F. J. Sprague, 321,141, June 30. *Train Signal*, M. F. Parrish and S. J. Munn, 320,495, June 23. *Switch*, L. Daft, 320,630. *Track Insulator*, same, 320,631, 320,633. *Railway*, W. Painter, 320,679.

Storage Battery:—J. DuShane, 320,232, June 16.

Telegraphs:—*Repeater for Quadruplex*, T. R. Taltavall, 320,311, June 16. *Type Wheel for Printing Instrument*, C. A. Mathiesen, 320,376. *Escapement for Printing Instrument*, Geo. B. Scott, 320,975, June 30. *Fire and Police Telegraph*, C. Selden, 321,058.

Telephone Systems and Apparatus:—*Mechanical Telephone*, H. and E. Seligmann, 320,181, June 16. J. R., J. D., and C. F. Holcomb, June 30. *Circuit*, H. S. Thornberry, 320,414. *Support*, T. W. Lane, 320,438. *Individual Signaling Apparatus*, E. F. Frost, 320,923, June 30. *Method of and Means for Preventing Interference in Combined Telegraphic and Telephonic Systems*, F. Van Rysselberghe, 320,987, 321,404. *Transmitter*, H. S. Thornberry, 321,323. *Duplicate Switch-board System*, C. E. Scribner, 321,390. *Multiple Switch-board*, same, 321,391.

Expired Patents.—A list of the more important electrical patents which expired during the month of July, 1885, together with those which will expire during the current month is subjoined:—A. C. Garratt, *Battery*, 79,567, July 7.—Edmands and Hamblet, *Dial Telegraph*, 79 741, July 7.—Biggar & Blood, *Burglar Alarm Circuit-Breaker*, 79,894, July 14.—Biggar, Blood & Griswold, *Burglar Alarm*, 79,895, July 14.—Bishop & Marks, *Machinery for Coating Telegraph Wire with Gutta Percha*, 79,896, July 14.—G. Natcher, *Railway Alarm Signal*, 79,915, July 14.—A. H. Castle, *Line Insulator*. 79,951, July 14.—J. H. Guest, *Thermostat and Alarm*, 79,972, July 14.—Same, *Burglar and Fire Alarm*, 79,973, July 14.—W. B. Allyn, *Mechanical Morse Transmitter*, 80,-049, July 21.—G. Little, *Telegraphic Recording Instrument* (*floating pen*) 80,293, July 28.—M. G. Crane, *Gong-Striker for Fire-alarm Telegraph*, 80,-822, August 11.—M. G. Farmer, *Duplex Telegraphy*, 81,485, August 25.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

NEW YORK, SEPTEMBER, 1885.

THE ELECTRIC LIGHT CONVENTION.

NOTHING can be more beneficial to the wholesome growth of a new business than an occasional assemblage of its practical workers, to learn from the experience of each other such facts as will prove advantageous to the whole body. Even the man who knows it all is benefited, for he is thus stimulated to renewed exertions by witnessing the earnest manner in which active, intelligent men are continually seeking for more light. Although two of the largest electric lighting companies were conspicuous by their absence, it is to be hoped they will eventually enter the ranks, and do their share toward establishing harmony between the various interests. Having personally watched the proceedings continually during the sitting in this city, we must confess our surprise at the thorough and impartial manner in which the rival interests were guided through the intricacies of debate on various subjects, without at any time giving a clue to the opinions of the members as to the merits of the different systems which they might represent. Those who did not understand this to be the case must have learned it before they went away.

The policy of the convention was defined by the sharpest possible line. A member was operating an electric light plant. He burned a certain amount of fuel; where was the fault, if any? Another ran his dynamos direct from small engines, while under similar circumstances in a different city a large engine with lines of shafting was used. Advice might be given to throw an engine into the scrap-heap, but the dynamo was not criticised. Those who seek to advertise their wares in a place of this kind must be very certain that they contain no flaws. It was a convention devoted primarily to the interests of those who produce and sell electric light, and the problem which is constantly before these gentlemen, whether at home or abroad, is the same which ever serves as the mainspring of progress: How can we secure the greatest return with the least expenditure. As a delegate expressed it, after adjournment, in conversation with a friend, "I do not care whether I supply the Brush, the Weston, or any other lamp, but what I do want is what I consider the best, and if I cannot get it from one maker I will from another."

It is frequently the case in a convention of this description, where members have come from a distance and at considerable expense and inconvenience, the question is asked, "What are we here for?" This would have been superfluous here, for it was apparent at every stage of the proceedings that all else was secondary to the interests of the active members.

It is plainly evident, however, that practical arc lighting is more closely allied to mechanical than to electrical engineering, or rather that economy in the operation of arc light plants is sought within the domain of engine, boiler, furnace or shafting rather than in the construction of the dynamo or the principle of the lamps. It is of more importance that the fireman should understand the principles of producing steam than that the electrician should understand the principles by which the dynamo produces a current. A dynamo is simply a machine that is driven at a certain speed, and produces certain results under fixed conditions. The steam boiler and the furnace will only produce certain results when carefully attended, as the conditions are continually fluctuating. The successful manager of an arc light plant is he who by practice and association becomes the most skilled in mechanical engineering. If such be the case the respective merits of the various dynamos are of less importance than the distance between the boiler and the grate, the quality of coal, or the skill of the fireman. The attention of dynamo inventors who seek to increase the efficiency of the machine is respectfully directed to the above thoughts, developed at an electric light convention.

ELECTRIC RAILWAYS IN PRACTICE.

CONSIDERABLE skepticism still exists as to the successful application of electricity to the propulsion of railway cars. There is a substantial reason for this, as it has been far easier to demonstrate on paper its advantages for this service than to actually introduce it as a substitute for direct acting steam or horse power. Admitting that such advantages exist, there are still sufficient differences of opinion as to the merits of various systems to account for the apparent delay in permanently adopting any of them. A thorough equipment of this character is not only originally expensive, but when once laid down it should remain, and for this reason, if no other, the best should be secured. There are no doubt many people who believe that the only preparation essential is to provide the required conductors, place a motor on a car, belt it to the axle, establish a dynamo plant at a convenient station, make the necessary connections, and "let her go." That might be putting matter in motion, but it would not necessarily constitute an efficient railway service; and taking the New York elevated railroads as a criterion, the supplanting of the present operating system is no child's play. A motor which is perfect in every other respect, but is given to

Digitized by Google

occasional fits of jumping the track, will not do, no matter how economical its operation may be. In the light of past experience it appears somewhat doubtful if a line already taxed to its fullest carrying capacity is the proper place to demonstrate the feasibility of an experimental system, not because it is unequal to the work, but simply for the reason that minor defects in such cases lead to serious results. Fifty years of steam locomotion have been necessary to the development of the modern railway. To suppose that this accumulated experience is to be heedlessly brushed aside, and that the electrical engineer, trained in another school, is to immediately provide a satisfactory substitute is the height of absurdity.

The popular idea of a railway operated by steam is a track, made up of iron or steel rails, over which trains of cars are hauled by locomotives. This is the final outcome of practical experience.

The electric railway, which has barely emerged from the guidance of its numerous inventors and exploiters, already exists in various forms, all of them being more or less crude. There is the overhead, the side, and the subterranean conductor, in all of which the current is derived direct from a dynamo; then there is the self-contained principle in which the current is supplied by a storage battery carried on the car. The latter system is intended more especially as a substitute for horse-cars. One inventor merely substitutes an electric for a steam locomotive, with its train of cars to haul, while another makes a motor of each car. Furthermore, no inventor appears to entertain proper respect for the systems advocated by his rivals.

One of the greatest drawbacks to a new branch of electrical industry, looking from a financial standpoint, is the continual march of improvement, forcing upon the management not only the adoption of new devices, but the actual abandonment of the apparatus which is superseded. This has been the experience in both the telephone and electric lighting fields, and there is no reason for believing that the electric railway will be an exception, especially as there is already a wide divergence in opinion as to the most desirable plan. While we have perfect confidence in the future availability of electricity as an economical method of applying power, it must be intelligently used. Its advantages can and will be demonstrated, and the various practical tests which are now being carried on in this country as well as Europe will eventually be crowned with complete success.

THE INCANDESCENT BRANCH OF ELECTRIC LIGHTING.

It is very probable that among those present at the recent meeting of the National Electric Light Association, there were a few who had not given proper consideration to the fact, that the arc lamp cannot be expected to supply more than from three to five per cent. of the artificial illumination of towns and cities. Its field is confined to street lighting, and in-door use in large sales-rooms, foundries, factories, and for such similar localities as experience has already shown it to be peculiarly adapted for. Statistics have also demonstrated the fact that the consumption of gas has actually increased where the electric light has been introduced.

The future extension of electric lighting must depend largely upon the success of the incandescent lamp, which has been comparatively neglected by those who have placed the arc system upon a paying basis. It has already been demonstrated in several instances that it is not necessary to underbid the existing price of gas in order to obtain a market for incandescent lighting. Its acknowledged superiority is so generally recognized that it commands a higher price, as is the case with numerous other commercial products.

There appears to be no substantial reason why the owners of existing plants now used solely for arc lighting should not undertake, cautiously perhaps, the gradual introduction of incandescent lighting, based upon the well understood commercial principle of demanding a fair profit. To do this properly will require more careful attention to the economical distribution of electricity, and success will depend in a great measure upon the skill and intelligence with which the system is arranged, and no doubt the same scientific supervision would in many cases lead to better results than have already been attained with arc lamps. Continued prosperity depends upon the occupation of new territory, as well as the active cultivation of that which has already been covered. It will very likely be found that towns which do not afford a lucrative field for arc lighting alone, may do so in combination with an incandescent system, provided of course that the population is largely composed of a class who not only appreciate its numerous advantages, but are able and willing to pay for them.

To those who are so situated that they can do so, we offer the suggestion that they fit up their offices with such incandescent lamps as they choose to adopt, mounted on those elegant fixtures which are now provided for that purpose. Let them satisfy themselves by actual experience as to the cost and desirability of extending their use. Local visitors, naturally attracted by the perfection of the light and its apparent adaptability for interior lighting, may be informed that it is not only very elegant, but very expensive. Eventually some person will insist on having it at any price, and having once secured its introduction, experience will doubtless lead to greater economy and corresponding profit. This may not be a really practical plan, but we believe the incandescent lamp is now fairly cut loose from the laboratory, and should be taken up at once as a branch of electric lighting for which there is now a profitable demand, to be extended almost indefinitely as the process of production be improved and cheapened, as it certainly will be in the hands of intelligent and ingenious men.

THE UNDERGROUND COMMISSION AND ITS WORK.

The various electrical companies having been duly requested to send in such plans as they might have devised for the burying of their wires, the Commission on Electrical Subways, located in pleasant quarters at the Metropolitan Hotel, calmly awaited their reception in order that they might proceed at once with the obsequies. Instead, however, of rendering that advice and assistance which as interested parties the companies might reasonably be expected

Digitized by Google

to offer, they all apparently with one accord began to make excuse.

One had made diligent inquiries throughout the civilized world, being not only willing but anxious to adopt a feasible plan, if there was such a thing in existence, but there appeared to be none.

Another, out of due consideration for the comfort of the commission, refrained from submitting any plan adapted to its own wires, because it might not harmonize with the system to be eventually adopted.

The representative of a district company stated that they owned no poles, and consequently had no street system, but that their attention was being devoted to subterranean plans, none of which appeared to be adapted to their service.

Having failed to obtain any suggestions from those who might be supposed to have thoroughly examined the history and practice of underground electrical work, the commission turned for relief to the inventors who have been laboring many long and weary years in this direction, each being the sole possessor of the only system which would appease the apparent wrath of the metropolitan editors who had sounded the death knell of overhead wires.

At last their opportunity had arrived, and the commission, previously embarrassed because no plan existed, found themselves equally at a loss to determine which of the hundreds presented was really the best. There were inventors with pipes, cables, and conduits; bare wires and insulated wires; curbstone, lampost and sidewalk systems; glass supports, porcelain supports and wooden supports. Here was an elegant reclining chair system, with a little railway along the bottom of a three-foot tube. Along its sides were to be arranged the various cables necessary to provide for the thousand and one conductors, while the subterranean lineman, recumbent in luxurious ease, was whirled along with celerity and despatch. Neither climbers, hatchet nor tie wires dangled from his belt. Judging simply from the surroundings and the serene expression upon his countenance as it appeared in the picture spread out for examination, the lineman considered the arrangement a success. There was a tinge of sadness in the negative replies which were made when President Loew blandly inquired of the several inventors if their systems were in actual operation.

We must admit that in our own nature there exists a certain repugnance toward going underground; but if we must go, we should elect to travel on a little electric railway in a reclining chair, our pathway illuminated by an incandescent lamp, and with continuous telephonic communication established for the benefit of ourselves and the friends whom we had left upon the surface above.

An impression prevails that no actual results have been accomplished by the commission. This is a grievous error. For many years the electricians of the various companies who were supposed to be interested in this important subject have patiently listened to the multitudinous variations which have been played upon this underground harp of a thousand strings. They have not been paid liberal salaries with their duties confined to this particular class of work; but when most deeply engaged in matters requiring uninterrupted attention their thoughts have been diverted by the entrance of gentlemen who had solved the problem, bearing with them models of fearful and wonderful construction, accompanied by samples of all varieties of natural products, and artificial compounds of rosin, bitumen, petroleum, glass, sand, sawdust and old gum shoes. All this is ended. The headquarters of the Commission on Electrical Subways is the Mecca toward which these pilgrims are now journeying. If nothing more is accomplished, the commission is fairly entitled to the thanks of certain deserving and hard-working members of the electrical community who have been diligently engaged for years in proving that their particular systems could not be made to work through underground wires.

A MYSTERY EXPLAINED.

The editors of this journal are always pleased to receive items of news of general interest from every quarter, and we think we may venture to say that the business manager is more than pleased to receive advertisements from responsible parties, for insertion, at the usual rates, in the columns set apart for that purpose, in which the advantages of the goods of the advertiser over those of his competitors are convincingly set forth, and his energy and enterprise duly extolled. Sometimes, however, careless people send the editor a news item with an advertisement concealed within it, which by some singular fatality fails to appear in either department of our journal. We think it due to ourselves to explain that this is on account of the office cat. This sagacious animal was brought up in an advertising agency. He was fed on advertisements, and has become as sharp-scented for them as other cats are for fresh fish. It sometimes happens that an item is sent us for publication reading something like this:—

The Jobson-Hobson Electrical Disseminating Company have just installed a plant, embracing one Robson generator and two tin handles, fitted with sponges, in the celebrated medical institute of Doctor Dobson, at Oshkosh cross-roads.

Dr. D., and a number of other prominent and enterprising citizens are so convinced of the superiority of the Jobson-Hobson system over that of Wobson, that they have formed a local company, of which nearly all the stock has been subscribed. The few remaining shares are advancing in value with unprecedented rapidity, and the backers of Wobson are becoming deeply discouraged.

This might, and probably in many cases would, escape the attention of the care-burdened editor, but it never escapes the attention of the office cat. It is a matter, so to speak, of bread-and-butter with him. Before the editor could protest, even if he wanted to, the office cat seizes and swallows the concluding paragraph, and carefully deposits the remainder upon the editorial table.

A WARNING TO PROMOTERS.

The tragic death of Albert D. Swan, of Lawrence, Mass., at the hands of a man who believed himself to have been wronged, should be seriously considered by those who engage in financial enterprises of a speculative character. There are too often beggared victims who, driven to desperation and heedless of their own lives or reputations, will not hesitate at murder in order to satisfy the spirit of revenge. There is frequently a cause for such an act which cannot be reached by legal punishment. If the golden rule was more carefully observed these tragedies would be less frequent.

ARTICLES.

THE BEST FORM OF DYNAMO.[1]

A VIEW of this subject allotted by our president, is rather a delicate task for one belonging to the rank and file of a dynamo builder. The problem of dynamo construction is susceptible of a large number of solutions, each form being the "best" if our claims as manufacturers are accredited. There is no distinctive feature, however, from which something cannot be learned.

The art has advanced so far from the experimental stage, that to-day we are enabled to judge of the merits or demerits of a new construction from a practical standpoint, aided only now and then by theoretical considerations. We have learned by costly experience that not always is that dynamo which gives absolutely the highest electrical efficiency the best for commercial results. We have found that the mechanical engineers cannot be ignored in the designing of electrical machinery; that the salient points in the best experience in construction of engines and analogous machinery should be closely studied and followed.

The best dynamo is that which with good economy operates continuously with the least expense; one that does not require the constant attention of an expert, by no means, however, underrating efficiency in an attendant; one which has no delicate parts liable to derangement, one in which all the parts are accessible for cleaning and proper attention. Large journals, heavy framework and substantial construction throughout are not to be overlooked in dynamo machinery any more than in a locomotive.

A tendency, which is becoming less prevalent, has been toward developing the greatest possible current with a given size or weight of machine. The construction in this case is generally too delicate, and all parts are overworked to such a degree that they are constantly giving way. The effect of this upon the commercial operator and public generally has been disastrous, establishing the impression that all electrical appliances are inherently unreliable.

The latter constructions are more durable, less delicate as to details, and generally more satisfactory; although it is true they may occupy a slightly increased floor space. The armature, being that part of the dynamo in which the current is primarily produced, it may be considered first in order. Its arrangement should be substantial, compact, and with as few irregularities as possible, which would tend to fan the air; yet be thoroughly ventilated, which is the most natural means of keeping down the temperature of the conductor. The core should in every case be laminated to prevent the generation of currents in the masses of metal. The armature conductors should not be too large for the same reason; and the mounting of the coils or armature conductor should be such as to avoid abrasion of the insulation from expansion and contraction, or from centrifugal action in or upon the same. They should, moreover, be accessible in all cases for cleaning and repairs. These coils being the seat of the development of the electromotive force, they should be so disposed that every portion, if possible, be subjected to the inductive influence of the field magnets.

I have taken special interest in this feature, and find that the average in the forms of machines ordinarily cited as examples is less than 50 per cent. for that portion of each convolution of the generating conductor which is productive of electromotive force, the remainder not only being idle, but offering wasteful resistance to the currents set up in the useful portions. The immense importance of this point will be readily appreciated and requires no further comment here.

Waste space on the armature should not occur, although unavoidable in some forms, such as the disc armatures. The mounting and relation of the armature should be such in regard to the field that no more than two magnetic reversals occur with each revolution.

The winding of the coils one upon the other is found to interfere materially in case of repairs, and is sometimes a fruitful source of short-circuiting, but cannot well be avoided in the cylindrical or Siemens form of armature.

The divisions of the armature conductor into coils should be as numerous as is practicable, especially where the electromotive force is high, as it facilitates the insulation of the various parts from each other, and lessens the sparking and consequent wear and tear of the collector or commutator. Another effect of increasing importance is a tendency to lessen the undulatory character of the current generated, rendering it more harmless to life, and at the same time reducing its inductive effect upon adjacent line wires, which so annoy our neighbors (?), who, I regret to say, are not always charitably disposed. (The remarkable facility with which some of our worthy contemporaries either detect or imagine the effect of induction from electric light wires is only comparable with the sensitiveness of the instruments which they handle.)

The commutator should be substantial, the insulation between the segments and at the ends should be ample, and of a character not liable to shrink, char, or absorb oil or moisture; the segments should be deep, to secure long service; the size should not be too small to secure proper electrical construction, nor so large that the friction of the collection brushes shall be felt, nor the centrifugal tendency on the segments operate to loosen them from their place.

The field magnets should be given special attention. Their arrangement should be that which would at once strike the practical mind as being the most natural. An effort should be made to avoid sharp angles or corners in both the polar extensions and the yokepiece at the rear.

The helices or coils should be of the most regular form, cylindrical being, perhaps, superior in point of economy.

The disposition of the quantity or masses of metal in the various parts of the field magnet should be also looked to carefully.

In some forms of machines a small core and coil may be found arranged to maintain the magnetic potential of a comparatively immense mass at the pole-piece. This arrangement is obviously bad. That form of electro-magnet most often met with in telegraph construction is, perhaps, of all forms, the best, and should be followed as closely as possible in designing fields for dynamo machinery. The arrangement of multiple coils parallel to each other for the magnetizing of a single pole-piece is adverse to high efficiency, as the adjacent parts of separate coils tend to mutually demagnetize each other. This effect should also be looked to with regard to the arrangement of other parts of the field magnets; often the polar extension and yoke, or any of the means by which the magnetic circuit is completed, are badly arranged as regards each other.

The arrangement of the field, as shown in the Gramme continuous current and Weston machines, that is, where the magnetic potential is developed midway in the length of the continuous core or piece of metal, labors under one disadvantage, which may be noticed as follows: Considering only one half of the entire field of the machine, which would consist now of two coils, a north and south pole and yoke, we have the ordinary electro-magnet; and the opposite facing the said first set, although integral therewith, would perform the office of a keeper and tend to satisfy the potential at the poles.

The current in the two coils on the opposite side of the poles must then do the double work of first overcoming this adverse tendency of the lines of the force and magnetic potential, and secondly, of aiding in maintaining such potential at the poles. This result is of course mutual with regard to the two sets of magnets facing each other.

1. Read by E. A. Sperry, of Chicago, before the National Electric Light Association, August 20th, 1885.

Digitized by Google

The efficiency, however, of this form of field is brought up to standard from the fact that only one half of the mass of the pole-piece depends upon each coil or helix for the maintenance of magnetic potential.

The distance between the pole-piece and the surface of a revolving armature should not be too slight. Experience has determined that the increased efficiency is more than neutralized by the increased heating effect; the space is more valuable for keeping down the temperature of the conductor upon the armature and lessening liability to damage resulting from a high rotative speed. Substantial bands should also be provided to guard against the latter.

It is of no little interest to note the changes marking the successive stages of development of any given machine as showing the effect of experience upon the more theoretical considerations, and bearings may be taken upon these successive stages which may guide the close observer in the selection of his apparatus, or the designer in the future development of any special form of dynamo machine.

A beautiful analogy may be traced between the distribution of the potential in the ordinary electrical circuit, and that in what may be known as the "magnetic circuit" of a dynamo. In the first the arrangement of the potential at various points depends upon the resistance encountered by the electric current at these points varing in degree with the amount of such resistance. This law holds true also in the magnetic potential at various points in the magnetic circuit of the machine. Here, the points of greatest resistance occur at the space which is between the polar extension and the armature core, and the degree of magnetic potential required at this point to perform the necessary work, will be determined by the distance between the magnetic surfaces at these points. For the highest economy in the field, therefore, this magnetic circuit should be closed, and no space whatever provided between said armature core and said polar extension. This, of course, being impossible, the aim should be as near an approach as is practicable, for reason that the cost of maintaining the magnetism of the field is the function of the degree of potential required at the pole-piece, and when this is low, only a small amount of current is required to maintain the field. In this case, a large iron core with a comparatively small amount of wire upon it, will suffice to do the work.

An erroneous idea, now going out of practice, has been to leave magnetic projections on the surface of the armature, which tend to short circuit and satisfy the magnetic potential of the field without compelling the induction to take place directly through the armature coils. The importance of as nearly closed a magnetic circuit as possible, was pointed out as early as 1873, by Lord Elphinstone, who, at that time, forecast the peculiarity which may now be seen as the result of practice and long experience in the art, viz: the distance separating the armature and field magnet, the masses of metal, the efficiency at the field and general construction of the machine are determined by the character of the current to be developed; the greater number of convolutions and the greater thickness of insulation between all the parts of the armature coil and its supporting core in case of high tension currents, requires a greater space for the coils, diminishing the size of the armature core and increasing its distance from the field.

The magnetic potential of the latter being therefore greater, its mass is lessened in both the pole-piece and core, with a proportionately large amount of wire, is required in the helices, and corresponding increase of energy required to maintain the magnetic potential. This peculiarity and difference may be seen in the two classes of arc machines. belonging respectively to the so-called high-tension and low-tension systems, and is even more readily apparent in the leading machines belonging to the two respective fields of electric lighting. This points to the fact that the internal efficiency of a machine varies with a certain function of the electromotive force of the current generated, being less for a high-tension machine and greater in a machine producing greater quantity and lower electromotive force.

In electric lighting there are many other features of vital importance, aside from the mere electrical efficiency of the generator; for instance, the cost of construction of lines, the distance at which the various operated devices may be maintained with economy, the economy of transmitting the current on the exterior circuit of lines, and possibly there also exists a difference in the transformation of electricity into light energy by the use of the voltaic arc—all, perhaps, in favor of the high-tension system; while the cost of maintenance, liability to leakage and attendant expenses, especially on underground systems, the danger to life and property, and the economy of construction and facility in coupling, especially in the incandescent system, are decidedly in favor of the lower tension.

The preponderance of the advantages in either of these systems must depend entirely upon the circumstances and upon the judgment of the investigator, no two plants being attended by exactly the same conditions.

The matters going to determine the best form of dynamo, as has been briefly pointed out, are so numerous, and the various forms of dynamos being best adapted each for its peculiar sphere, that a general formula, prescribing that form which is best in all cases, would be impossible. The art, however, has brought dynamo machinery, the construction of which at first was attended by so many difficulties of a high scientific nature, down to a sufficiently practical basis, so that good judgment with regard to ordinary mechanisms of a higher order are relevant to the more salient features, and may be depended upon largely in guiding those interested in investigating this class of apparatus.

THE ELECTRIC RAILWAY IN NEW YORK.[1]

BY F. A. PICKERNELL.

For several years past, the question of running the New York elevated railroads by electricity has been agitated. This culminated in a meeting held in New York city on the 18th of November, 1884, at which were present representatives of the Edison, Daft, Field, Siemens, Brush, and Bentley-Knight electric railways, and also of the New York elevated railway. At this, and five subsequent meetings, it was decided to test each system of applying electricity as a motive power for railways upon a certain portion of the elevated road. To pass judgment as to the relative values of the various systems, the following gentlemen were appointed to form a board of arbitrators: Sir William Thomson, Prof. Charles R. Cross, George B. Roberts, James H. Rutter, and Robert Harris. It was, moreover, decided to finish the test, if possible, within 90 days. This time has long since elapsed, and the waiting public have heard no report.

During this time, however, a vast amount of work has been done, and great difficulties surmounted. The great delays have been occasioned by the mechanical application of the electric-motor to the heavy and quickly moving trains. In the various systems to be tested, a third rail will be employed; and the laying of this, combined with its proper insulation, has consumed a vast amount of time.

In spite of all difficulties, the Daft company have completed their preparations, and are ready to start. As in other systems, the electric circuit is made from the dynamo to the central rail, through the collector to the motor, thence to the wheels and rails, and back to the dynamo. This company have laid their third rail upon the Ninth avenue line, commencing at 14th street. This rail is insulated by the Daft patent insulator, which prevents water from making a connection from rail to sleeper, thus insuring good insulation in all weathers. The road is further equipped

1. *Science.*

Digitized by Google

by completing the electrical contacts at the joints of the outer rails.

At the end of this line the company have located their central station. They have placed in position a large William Wright engine, with the necessary boilers and shafting. Two 50-h.p. Daft dynamos are now in position, and, later, a third will be erected to relieve the others, in case of accident. The wires are carried from the station to the rails through the streets upon poles.

The motor, Benjamin Franklin, has been for some weeks finished, and has been thoroughly tested. The motor is fourteen feet six inches long, and six feet nine inches wide, and weighs nine tons. The schematic drawing, fig. 1, will show the manner in which the motor is arranged. No attempt is made here to reproduce the proportions of the Benjamin Franklin. One of the largest-sized Daft motors,

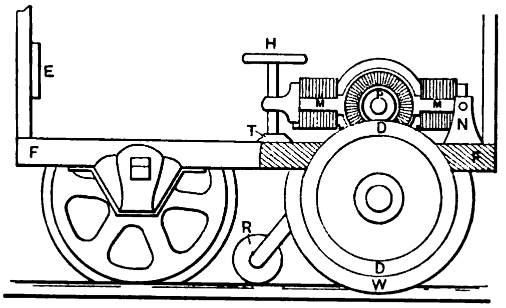

Fig. 1

MM, is mounted upon the truck FF. The motor is hung so that it turns about N as an axis. The other end is supported by the screw H. The maximum capacity of this motor is 300 ampères, with an electromotive force of 185 volts. The power is transmitted from the motor to the wheels by the grooved friction-gearing P and DD. P is keyed to the armature shaft, and DD to the drive-wheel shaft. The flange of the drive-wheel, on the farther side, is shown at W. These gears are duplicated on the other side of the motor. The amount of pressure upon the friction-gears is regulated by the screw H. This screw is also advantageous in case of repairs, for by means of it the motor may be moved completely off its friction bearings. The support, N, of one end of the motor, is cushioned with heavy strips of rubber, as is also the cap T, upon which the screw rests. The trucks are likewise cushioned, thus allowing freedom of motion in any direction, and insuring perfect accommodation, on the part of the motor, to any irregularities in the road-bed.

The connection with the middle rail is made by means of a heavy bronze wheel 14 inches in diameter, R. This being fastened to an arm, may be raised or lowered, thus allowing discontinuities in the central rail, of which there are several in the Ninth avenue line, to be safely passed. The wiring is all underneath the frame, and is enclosed in wooden sheathing. The device for controlling the motor is placed at the end of the cab at E. This is a device of sliding contacts, worked by a handle similar to the throttle in the locomotive-cab, which raises or lowers the resistance in the field-magnet circuit, thus varying the amount of current, and consequently the strength of field and speed of motor. There is also a complete cut-out in circuit. The motor is thus under complete control, it being possible to run fast or slow. The motor may be stopped either by the cut-out, or by lifting the contact-wheel. The system is further provided with an automatic cut-out, which breaks the circuit when the current reaches a certain strength, at the same time ringing a bell at the central station, warning the engineer at the central station that there is trouble on the road.

The reversing-gear is simply four brushes connected by suitable links, so that a movement in one direction applies one pair of brushes, while a movement in the other applies the opposite pair. In the motor Benjamin Franklin, the ordinary hand-brake will be employed; but later, some form of air or electric brake will be used. This motor is a very substantial affair, as its weight (nine tons) would show. The experiments will be performed as soon as Mr. Daft is at leisure to commence them.

The Edison and Field companies have combined, and are preparing to test their system upon the Second avenue line. The length of this line from Chatham street to Harlem is 7.44 miles, only part of which, however, will be traversed by the electric railway. Although this company have not brought their work so near completion as the Daft company, still they have done a deal of hard work. They have located their central station upon 24th street, and have provided there a 250-h.p. Whitehill & Smith engine, with the necessary boilers and shafting. The Edison dynamos have not yet been set in position, nor has any wiring been done.

In this system, the central rail has to be very carefully insulated on account of the comparatively high electromotive force employed (some 600 volts). To this end, the rails will be insulated by resting upon glass shoes, which will be protected from the jar of passing trains by a thin strip of rubber. As the glass shoes have not been delivered, the rails have not been laid.

The work upon the motor has progressed slowly on account of the many difficulties offered. The original arrangement, shown in the *New York World*, April 26, 1885, has given way to several newer forms suggested by it. The latest form, and the one to be completed, is shown in the schematic drawing, fig. 2.

In this system, every truck will be provided with a motor, thus making every car independent. In fig 2, A is

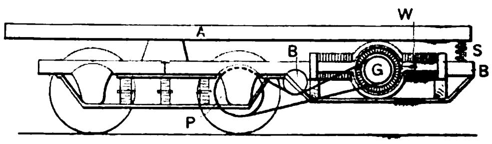

Fig. 2

the bottom of the car, T is the ordinary railway truck used upon any car. To apply the motor, the truck is prolonged to B, and is supported by the springs. This spring is hung from a roller capable of side motion, thus allowing the truck to accommodate itself to curves. The motor used is a compound-wound Siemens, and is so designed that, with an external electromotive force of 600 volts, it will revolve at a constant speed of 600 revolutions per minute. The power is transmitted from the armature to the pulley C by means of a Weston friction-clutch. This friction-clutch, W, is worked by a wheel similar to the ordinary brake-wheel, one wheel working both friction-clutches of one truck. The power is transmitted from the pulley G to the pulley P, keyed to the axle of the driving-wheels, by means of a heavy leather belt of peculiar construction. In order to obtain more bearing surface for the belt, it is carried around the pulley B. This same arrangement is reproduced on the other side of the truck.

The motor itself is movable, so that the tension of the belt may be varied at will. The contact with the middle rail is made by means of brushes sliding upon it. The brushes are mounted on the ends of a bar which prevents their dropping down when another road is passed, and thus short circuiting the track. The brushes are held in position by springs which allow them to turn, and thus insures a drag of the brushes at all times, instead of a push, thus allowing the joints in the rails to be smoothly passed. The reversing is accomplished as in the Daft, by employing an extra pair of brushes. The speed of the car will be controlled by the friction-brake, the motor running constantly at a uniform speed. The Eames vacuum brake will be employed, the pump of which will be run by the motor.

It will be seen from the above, that the Edison-Field

Digitized by Google

combination are working upon a new principle. This system will have many advantages peculiar to itself. Each car will be independent, and the cars composing the train will start off simultaneously, thus relieving the elevated structure of the great strain caused by the locomotive when starting. The constantly revolving armature, on account of its high speed, and consequently great momentum, will help start the train, thus relieving the engine at the central station of sudden and great strains. As the load on the car increases, the traction likewise increases. The weight, moreover, of a train of this kind, is more evenly distributed than in one moved by a locomotive.

The electric motor, in general, possesses advantages which are of special value on an elevated road. It is possible to balance an electric motor, thus relieving the structure of the constant vibration caused by the quickly moving locomotive. Its freedom from dust and smoke, as well as its economy, insure its immediate introduction.

Although the progress in introducing the electric motor on the New York elevated railway has not been so rapid as had been anticipated by enthusiasts, still the progress has been steady, and in the right direction. It is, perhaps, remarkable, that more companies have not commenced operations ; but when the magnitude of the task is realized, and the patents held by a few parties are inspected, the reason is seen. However, several other companies intend to commence operations in the immediate future, the plans of which are now maturing.

BAZIN'S ROTATIVE BATTERY.[1]

This apparatus, which is designed for electric lighting purposes, is a combination of Poggendorff's bichromate battery, and of mechanical depolarization by rotation. While the principle is not new, the careful tests of its efficiency which have been made will be found of interest to those who are experimenting in this direction. The arrangement adopted is shown in figure 1.

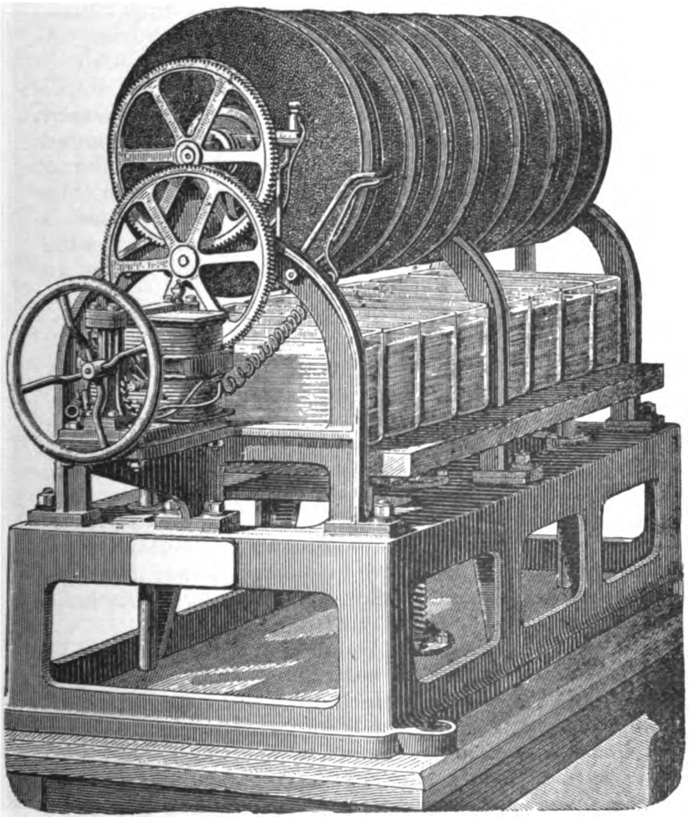

FIGURE 1.

The zincs and the carbons are mounted upon one and the same axle, to which a slow and regular rotatory movement is communicated by the aid of a small electric motor supplied by a distinct element. The battery represented in figure 1 comprises eight elements, seven of which are utilized in the outer circuit; each element is composed of a disc of zinc placed between two discs of carbon; the liquid is contained in rectangular troughs, which hold each three litres. The immersion of the elements is regulated by raising up a platform on which all the troughs are placed. The immersion may vary from zero to one-third of the surface of the discs, according to the degree of exhaustion of the liquids.

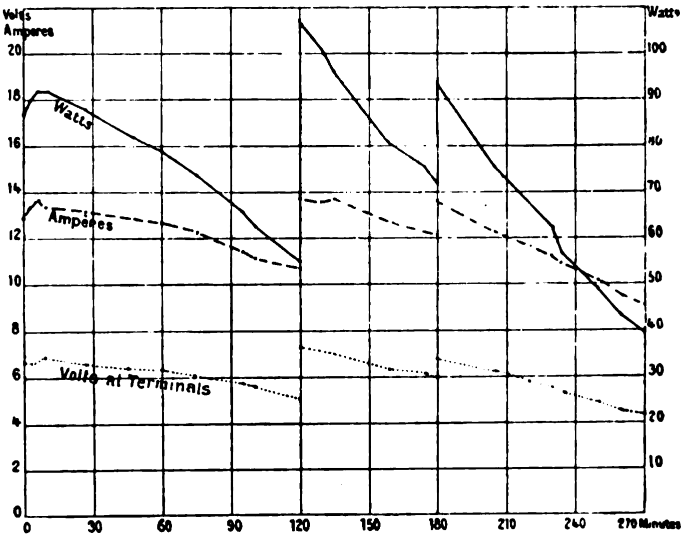

FIGURE 2.—Diagram of the Discharge.

The diameter of the discs, and the number of the elements in series, may be made to vary according to the duration of the effects to be produced in the outer circuit. M. Bazin has constructed other models with oscillating elements, but we have not had the opportunity of experimenting with them. In all, the movement is communicated at once to the carbons and the zincs, which in our opinion is an inconvenience, since the liquid conveyed out of the element by the zinc during rotation is used in pure loss.

However it may be, here are without comments the results obtained in the best of the three complete discharges which we have had the opportunity of effecting with the rotative battery.

The battery used in the experiments comprised eight elements; one of these elements served to supply the motor which gives the axle supporting the zincs and the carbons. a rotation of about one revolution per minute; the other seven elements are connected in series on the outer circuit. This outer circuit is composed, beside the connecting wires, of a resistance of 0·1 ohm in nickel silver, 6 millimetres in diameter, four Cruto lamps of 6 volts, arranged in parallel, and an ampèremeter.

The current was measured by taking the differences of potential at the extremities of the resistance of 0·1 ohm with a movable frame galvanometer (Deprez-d'Arsonval's model) previously calibrated by a total resistance of 2,000 ohms, and giving under these conditions 50 divisions per volt on each side of the scale. The sum of the two readings gave the current directly in tenths of an ampère.

The same apparatus enabled us to measure the differences of available potential at the extremities of the battery, by raising the total resistance of the circuit of the galvanometer to 10,000 ohms.

The arithmetical mean of the two readings of each side of the scale gave this difference in tenths of a volt.

The corresponding available power in watts was ob-

1. M. Hospitalier in *L'Electricien.*

Digitized by Google

tained by multiplying the current by the difference of potential.

The total quantity of electricity supplied, as well as the total electric energy, were obtained by measuring the corresponding surfaces of the subjoined diagram, figure 2, by means of Amsler's planimeter.

Each of the elements contained 3 litres of liquid. This liquid was an acidulated solution of bichromate of potash; 125 grammes bichromate, and 300 grammes sulphuric acid per litre.

The discharge was effected in three stages:

1. Continuous discharge for two hours (from 0 to 120 minutes). Stoppage of 2 hours 20 minutes.

2. Continuous discharge for one hour, with a greater immersion of the elements (from 120 to 180 minutes).

3. Total immersion of the elements and continuous discharge for 90 minutes, without stoppage between the second and the third stage.

The elbows of the curves at the points 120 and 180 minutes indicate distinctly the augmentations obtained in the yield by the decrease of the internal resistance resulting from the increase of surfaces.

The subjoined table summarizes the principal conditions of the total discharge, the factors of which are shown at each instant by the diagram, figure 2.

Duration of discharge..................	4½	hours.
Quantity of electricity supplied..........	198,000	coulombs.
" " "	55	ampère hours.
Total available work....................	0·45	h. p. hour.
Total consumption of zinc (motor not included)...............................	1126	grms.
Mean consumption of zinc per element...	160·9	"
Effective consumption per ampère hour..	2·93	"
Theoretic consumption..................	1·213	"
Ratio of the two consumptions.	2·4	"
Mean power of battery during a discharge..................................	75	watts.
Mean power of an element..............	10·74	"
Maximum power of an element..........	15·	"
Initial electromotive power (7 elements in series)..............................	13·1	volts.
Final do. do.	11·9	"

If we calculate the consumption of the battery as referred to h. p. hours, and taking account of the circumstance that the seven elements during this discharge have yielded 0·45 h. p. hour, we find in round numbers:

Zinc..................................	2½	kilos.
Bichromate of potash..................	5½	"
Sulphuric acid	13	"
Total volume of solution...............	45	litres.

Such are the present working conditions of the Bazin battery. To justify the insufficiency of these results, M. Bazin points out that our experiments have been made with the first apparatus constructed for his own studies, and necessarily incomplete. He promises by October next more perfect apparatus, in which we shall find decided improvements. We shall therefore await further experiments before passing a final judgment.

THE COMPASS IN IRON SHIPS.

THE Philadelphia *Times* gives an interesting account of a curious industry—adjusting the compasses of iron ships. The business, it says, is monopolized by three persons in the United States—two in New York and one in Philadelphia. An iron ship, said one of these professionals, is a great magnet. The magnetism of such a ship is technically known as "permanent," from having received the same from some other magnet itself styled permanent. The position the vessel occupies in the shipyard while in course of building is the principal feature in the shaping of her magnetic influence. It may seem incredible, but a vessel lying due north and south on the stocks will be highly charged with magnetism—so highly, in fact, that the nicest calculations and most skillful adjustment of neutralizing magnets is requisite to correct its influenee on the compass, and with the greatest care errors are made, which involve more or less trouble in the directing of the ships' course.

Every blow struck upon the iron plates of the sides, upon the rivets, or even by the calker, has a pronounced effect upon the ship's magnetism. It is well known that in certain processes of iron working, workmen, after striking the metal in one direction for a few minutes, are compelled to reverse the direction of their blows so as to change the polarity in order to prevent the fine particles of loose metal from adhering to their tools. In ship building it is impossible to reverse the manner of striking, and the result is that the magnetic currents are not equalized.

If a vessel that was built north and south in the yard travels generally north and south she loses a great portion of her magnetism, and a corresponding change is noticeable in her compass.

The lines of magnetism always run in a contrary direction to the position the ship occupied in building. It is said that the quality, ductility and grain of the metal used in the construction of the vessel have a great deal to do with the magnetic currents. It sometimes happens that the greatest accuracy that can be secured will not prevent a variation of three or four points from the true point. Occasionally it happens that, for illustration, a variation of but one point will be noticed when the ship is headed northeast, but when headed southeast five or six points of variation exist. The magnets used to neutralize the ship's magnetism consist of large bars of iron, spheres, spheroids, coils and, in fact, iron of almost every shape. These are placed in different portions of the vessel and exert a greater permanent influence the further away they are placed. When placed near the compass they "make the needle wild." If the engines are changed during the trip, if new boilers are shipped, iron taken aboard or "patches" put on the sides, the magnetism of the ship is proportionally disturbed and a readjustment is necessary. Usually an adjustment for all practical purposes will secure safety, so far as the compass is concerned, for a year or probably longer; but cases are reported where iron ships but forty-eight hours out from port have been wrecked in consequence of a change in the ship's magnetism producing a variation of the needle not calculable. These are rare, however.

ELECTRIC LAUNCHES IN THE RUSSIAN FLEET.

As a result of experiments made by the Russian War Department last summer at Cronstadt with electric launches, a part of the Russian cruising fleet has been supplied with these vessels to be used for night attack. The design is by Lieut. Treritinoff. Each launch carries an electric battery of 200 accumulators, which, section by section, are capable of furnishing propelling power for from 15 to 20 hours, and with a velocity of from five to six knots the launch is good for from 75 to 100 miles.

These launches have been found peculiarly adapted for carrying an armed crew on warlike expeditions at night, because, unlike the steam launch, they make no noisy puffing and are good for a long distance. Boats, even with muffled oars, are more or less noisy, and, besides, are very slow. Here, then, is a case where the electric launch is invaluable, because economy, of course, is not a requirement, speed and silence being the requisites.

We are not told how many men these launches will carry, nor how many are assigned to a single vessel. They can be swung over the side and launched from davits like ordinary boats, the men boarding after the launch is safely afloat.—*Bulletin des Telephones.*

THE UNDERGROUND WIRES OF CHICAGO.

BY C. C. HASKINS.

The interest felt just now in electrical circles on the underground question, the action taken by various cities of the Union, looking to the removal of overhead wires of every description, would seem to render apropos a history of this whole matter, not only for information, but to give to the originators the credit for an idea which has been canvassed, pro and con, throughout nearly the whole civilized world, and place its local progress here on record for future reference. In practical underground electrical work, embracing all systems, Chicago is in advance of any city in America, if not in the world.

THE ORIGINAL IDEA.

The history of the present underground enactments dates back as far as 1875. In that year our present city electrician, Prof. John P. Barrett, then chief operator of the fire alarm department of Chicago, drafted a resolution embodying the vital parts of the existing enactments. This resolution was introduced into the city council and referred to the committee on fire department, where it was earnestly fought by Gen. Anson Stager, Norman Williams, Esq., superintendent J. J. S. Wilson, and Chas. H. Summers, electrician of the Western Union company. Mr. E. B. Chandler, then superintendent of the city fire alarm department, also doubted the wisdom of the resolution, and it was finally placed on file—pigeon-holed in the desk of the committee.

Matters now rested in *statu quo* until Prof. Barrett by promotion had been made superintendent of the fire alarm department, when, not having seen any reason for change of opinion, he renewed the warfare on overhead wires. In the meantime no little inimical feeling had been engendered in the minds of his opponents, and the "ground hog ordinance," as it was facetiously called, and the "original ground hog," were the subjects of many a pleasantry, and bitter comment as well.

THE ORDINANCE BEFORE THE COUNCIL.

At the council meeting of May 2, 1881, the committee on judiciary, to whom the ordinance of Prof. Barrett had been referred, consisting of Daniel L. Shorey, John M. Smyth, and John M. Clark, reported favorably and recommended its passage. Alderman Clark moved the report be laid over, which motion prevailed.

The ordinance succinctly forbade the erection of any new telegraph work in the central portion of Chicago after the 1st of January, 1883; within a farther limit, after the 1st of January, 1884; and throughout the rest of the city after 1885, with a penalty of $100 for each offense for each wire, pole, or line, or electric conductor erected or maintained in violation of the law. All permits previously given were to terminate and cease at the dates and in the districts mentioned, the penalty being $50 for each and every day the violation should be continued after the 1st of January, 1885; ordered all electrical conductors placed underground, subject to the supervision and control of the commissioner of public works, and required special permits from that department. The city lines were exempted.

Subsequently, during the same year, the present existing law was passed as a substitute for the previously proposed ordinance. The provisions of this ordinance may be briefly stated as follows:

Sec. 1 forbids any and all new work within the city limits, under penalty of $100 for each offense, and each day of continued maintenance shall constitute a new offense.

Sec. 2 forbids the maintenance of any existing lines after May 1, 1883, under penalty of $50 for each wire, pole or line, each day it is so maintained in violation of law.

Sec. 3 requires all existing lines to be laid under the streets and alleys of the city.

Secs. 4, 5, 6 and 7 specify how, when, and where the work of burying the lines shall be done. The law to take effect at once.

THE LAW EVADED.

Matters had now reached a crisis, and something had to be done. The constitutionality of the ordinance was questioned, the right of the city to revoke previously granted permits was doubted, and while repairs were permitted at all times on proper application to the superintendent of the fire alarm telegraph, every now and again bright new wire and insulators grew to their places in the dusk of night or gray of the early morning; and despite the spirit of accommodation and leniency for which the "original ground hog" is proverbial, there were occasional difficulties with parties who became defendants in suits for violation of the law.

In a commendable spirit of accommodation a special provision was made by the council permitting a line of poles and wires from 39th street, along Clark, to enable the Mutual Union to get their southern lines over the forbidden ground to their office, at the request of that company. This contained a proviso that these should all be removed by the 1st of May, 1883, and in default of such removal the Mayor was empowered to cut the lines without notice to the company.

OVERHEAD WIRES OFFICIALLY CUT.

On the day named the lines were intact, and working as usual. The Mayor had instructed the superintendent of city telegraph to be ready, and during the day, accompanied by a corps of assistants, he went quietly to the city limits, south, and proceeded to sever the lines.

The destruction of the entire line of 60-foot poles, which would undoubtedly fall if the strain was removed by cutting the wires, was a serious matter, and might possibly result in further destruction of the property of innocent parties, if indeed it did not peril life. In order to sever every wire without subjecting the line to this sudden and tremendous strain, only one wire was cut between each two consecutive poles, the next circuit being cut on the next section, thus distributing the unusual tension throughout as many sections (30) as there were conductors on the poles.

The surprise of the operating department at the main office was as perfect as the discontinuance was complete. One after another line gave out mysteriously, until an oppressive silence reigned where but a few moments previously, all was in perfect operation.

THE QUESTION IN THE COURTS.

The matter was carried before the city council, and eventually into court for adjustment. The judge before whom the case came decided that inasmuch as the telegraph company had accepted the law and agreed to abide by its provisions, there was no enactment which would legally permit them to replace the disconnected lines; that although the severing of these wires by the authorities was irregular, being once severed they could not legally be re-connected by the company.

The matter was finally compromised, the company being permitted to repair the damage and continue business, subject to certain restrictions, the company agreeing to use their utmost diligence in replacing their overhead wires by underground lines, substituting the latter for the former as fast as consistent with uninterrupted service, and the discontinuance of these overhead lines left to the discretion of the authorities.

The Western Union had in the meantime obtained an injunction against the city, preventing its interference with their lines erected before the ordinance was adopted. As a matter of compromise, to test the validity of the law, a test case was agreed upon by the city's legal advisers and the attorneys for the telegraph and telephone companies, and in the interim plenary powers were delegated to the

Digitized by Google

city electrician, to deal with the latter parties as in his judgment seemed best, his action being governed by the willingness or refusal of the companies to perform their part and use due diligence in carrying out the provisions of the ordinance. The injunction obtained by the Western Union was aimed against interference with the maintenance of lines already up when the ordinance was passed, but had no reference to new work.

THE BEGINNING OF SUBTERRANEAN WORK.

At the meeting of the council, July 31st, 1882—to digress a little—the Chicago Sectional Electrical Underground Co. came to the front. By enactment of that body, Henry Corwith, Wm. C. Grant, Edward S. Dryer, Wm. H. Bradley and Edward Koch were granted, for a term of 25 years, permission to construct and maintain conduits throughout the city, for electrical purposes. The act provided that all the lines of conduits should be underground, save at the tunnels, and under the supervision and control of the commissioner of public works—subject to any future legislation relative to underground lines—and to be commenced within six months from the passage of the act. The ordinance required them to permit others to use their conduits, and in case of dispute as to rental compensation, the terms to be settled by three arbitrators. The company may form a corporation. The usual restrictions as to space occupied, damage to and repairs of thoroughfares, etc., including a bond of $5,000, with sureties, are embodied in the ordinance, and the personal liabilities of the several parties are defined.

The Postal Telegraph Co. was then demanding right of way into the city. A contract was entered into with Elisha Gray by the underground company, and a conduit was laid between the Postal office, corner of Lasalle and Washington, and the city limits. This conduit, the first and last of its kind, probably, was a rectangular iron box, constructed of ¼ or ⅜ iron, in sections, fastened together. The box was covered with an iron lid, and within were placed two Patterson cables, which are still in use by the Postal company. The size of the box is about 6 x 8 inches. The Underground company is to-day using a far different conduit, both as to shape and material, as will be seen below.

The credit of originating the underground idea, as we have seen, belongs to Prof. Barrett; but in addition to this, he is entitled to the credit of having first carried the plan into successful operation, and this is how it came about. A portion of the most aristocratic residence locality on the north side lay along a projected line of fire alarm telegraph, and in order to successfully build the line without legal interference, the superintendent made all the necessary preparations, and one fine Sunday the good church folks saw a handsome line of poles and wires erected before their very eyes, without a possibility of preventing the desecration.

There was almost no end to the complaint. The immediate discharge of the head of the city fire alarm department was imperatively demanded. A council of war was held, and the professor's only suggestion was that the wires should go underground, for which a specified sum was asked, and the next morning the money lay upon his desk. The wires (kerite) were laid in iron pipes coated with coal tar and oil, and the pole line removed. This was in 1876, and the wires are to-day, after nine years continuous service, as perfect as ever, and still doing daily duty.

"This one-half mile of conduit," according to one of the system's bitterest enemies—who has since changed his mind, by the way,—"this little piece, put down by Barrett, is what has raised hob with us all."

The next attempt was made here in the winter of '78–'79. A "Brooks" oil cable was placed in the Washington street tunnel, containing 50 wires for the fire department, and the following spring a similar cable was placed for the telephone company in the same tunnel, and two similar cables in the Lasalle street tunnel. These were oil cables—or cables run through iron pipes filled with oil—at one extremity of which a tank supplied oil for any minute leaks that might occur.

The fire department pipe has been discontinued. The telephone company are still using the Washington tunnel cable, with good results. A fire last spring destroyed the north terminals of the Lasalle tunnel, and a Patterson cable was substituted.

In the fall of 1881, Geo. W. Bonnell brought out an underground system, which was peculiar to say the least of it. Each wire was drawn through thin glass tubes, and these, placed in lead pipe were surrounded by a waxy insulation, a compound of paraffine and tallow, or something similar. The theory was that while the cable might be bent and the glass broken, the fragments would prevent contact, while the insulation would be impervious to moisture. Naked wires were used.

A line of this was commenced in 1881, from Washington near Dearborn street, to about 26th and Stewart avenue, for the Chicago and Western Indiana R. R. Co., and another piece for the Mutual Union—which at that time was being opposed by the W. U. company—down Dearborn street. Both these cables were abandoned as worthless, neither being completed.

In the summer of 1882, a 20-wire Patterson cable was laid for the same railroad company, from 94 Washington, over the same route as before. On the completion of the company's new depot at Polk street this year, the portion north of Polk was abandoned.

In 1883 the two cable iron box conduit mentioned before, connecting the Postal company's office with the city limits was laid.

Of underground conduits we have had several forms. The Western Indiana cables were laid in wooden boxes, without other protection, the Postal in an iron box—both of which are well filled to-day with silt—the B. & O. company used wrought iron pipes laid in a box filled with asphalt, containing Clark, Day's kerite, and Patterson wires, the Western Union laid kerite wires in iron pipes, the city adopted the Dorsett pipes with kerite wires, the telephone company have both kerite and Callender cables as well as Patterson. The Bankers and Merchants' used kerite wires, in iron pipe.

In addition to the above a short section, some 300 feet, of a novel underground arrangement is in use in Lincoln Park, which contains the positive and negative wires of an arc plant. The compound here used is a plastic insulator, in a wooden box about 3 by 5 inches, in which the naked wires are strung upon porcelain insulators. This has been in regular use for some four or five months, and is working in a perfectly satisfactory manner.

While on several occasions there have been casualties arising from the influx of sewer or burning gas in several of these conduits, there have been none of that nature, that I am aware of, in those formed of the Dorsett material, which as a narrator of facts I feel bound to state.

The iron pipes used by the Bankers and Merchants' have been unfortunate in this regard on two or three occasions, and the Western Union came near losing two valuable men by a similar catastrophe. Mr. Summers, electrician, and Mr. Brotherhood, engineer, were both badly injured by an explosion of burning gas.

The presence of gases in these pipes is destructive to all forms of gutta-percha, Chatterton's compound, etc., used in joining wires, and the only remedy seems to be, in some form, to keep these gases out of the pipes, for the two-fold purpose of protecting joints and preventing either suffocation or dangerous explosion, when man-holes are opened for repairs or inspection; and this air, gas, water, oil or sewage prevention has thus far only been accomplished by the Dorsett conduit.

January 23, 1885, corporation counsel F. S. Winston, Jr., in response to a request for information, made a re-

Digitized by Google

port to the council, embodying a letter from J. P. Barrett, superintendent city telegraph, in which the following figures appear, showing the approximate miles of wires already placed beneath the streets and alleys of Chicago:

Bankers and Merchants' Telegraph Co.	400	miles.
Postal Telegraph Co.	180	"
Chicago Telephone Co.	28	"
Western Indiana R. R. Co.	50	"
City Fire Alarm Telegraph	60	"
A total of	718	"

"In addition to these, preparations are made, or being made, by which as soon as possible there will be placed by the W. U. Telegraph Co., 500 miles; Baltimore and Ohio Telegraph Co., 250 miles, approximately."

Such was the status of affairs at the opening of the present year. Of course nothing in the way of progress could be accomplished beyond preparation, until frost was out of the ground. As soon, however, as the weather permitted, active preparations were commenced and the work rapidly pushed forward during the season.

One short paragraph from an interview with Prof. Barrett, on the occasion of a Philadelphia committee's interview in December, 1883, may briefly give his opinion then, which experience has not changed. To the question, "To sum it all up, then, you consider that the city has adopted the best form of conduit yet invented?" he answered:

"The best answer to that question is the statement that I have spent five years examining and testing devices for this purpose, and have finally recommended the use of the Dorsett system by the city."

Not a dollar has been paid by the city in repairs in any one of these conduits.

A new form of cable box is being laid by the Western Electric Co. for the Chicago Telephone Co. This consists of Patterson cables in a wooden box, which is subsequently to be filled with cement.

Nine hundred wires will be thus laid in the west division. The Standard Cable Co. have a similar contract for 650 wires on the north side.

There are at present, of various forms of underground conduits and cables within the city limits something over 400 miles of wires laid by the Western Electric Co., and these embrace every variety of wire from electric light to telephone conductors; 516 miles additional are now being laid by this company.

The Sectional Underground Co., using the Dorsett conduit, have made a checker board of the city, their routes running through every alternate street on the south side from the main river to Van Buren street, and from the south branch to the lake, an area of about 2½ miles square. They have in this space, each trench containing two pipes, 22,100 feet of conduit, which, with fourteen 2-inch holes in each pipe gives an abundance of room for the needs of the city and the various companies for a long time. On the north side there are 10,420 feet of this double conduit laid and the work still going on, while on the west side they have hardly commenced, having but 4,460 feet down. The total of Dorsett conduit down to-day is a little over seven miles, each representing fourteen longitudinal round spaces of two inches diameter. Electric light systems are thus separated from wires carrying lighter currents.

The city, too, is continuing the work. The arrangement of the system is such that every block is easily reached, either from front or rear, and Prof. Barrett is pushing the work as rapidly as possible. From every box the wires will dive at once beneath the sidewalk, and thence out of sight around the block, if need be, to the nearest lateral, not to appear again above ground till it reaches its central station.

In the course of a few days not a wire belonging to the city will show above ground, on the south side, and the north and west divisions will be cleared soon after; while in a comparatively short time all the overhead wires which have been so loudly complained of, will have departed from our city's thoroughfares forever.

PRIVATE INSTALLATIONS OF ELECTRIC LIGHTING.[1]

BY RALPH H. C. NEVILE.

Having for many years desired to use the electric light for domestic lighting, the author could not see his way to doing so while arc lights—and those anything but perfect—were all that were commercially practicable. When, however, incandescent lights were introduced, he determined to make the experiment as soon as possible. Happening to have a six h.p. portable engine some ten years old, which he had been using for pumping and for driving a saw, he determined to try this for the purpose, although warned that in all probability difficulties would arise in respect of the governing, as proved to be the case, in consequence of the governor being one of the old-fashioned kind, with heavy balls revolving at a slow speed. In the course of last summer he arranged with Messrs. Edmundson, Westminster, to carry out the wiring of the house, and in the autumn obtained from them a Siemen's SD 9 compound shunt-wound dynamo, and completed the installation sufficiently to judge of the merits of electricity *versus* gas, which had been the previous illuminant. The total number of lamps in the house is 125, divided over some 50 rooms and offices. The maximum number of lamps hitherto required at one time for purposes other than those of experiment has been 60. All the main wires within the house have been laid to admit of the full number being used, and even of an increase to 150 or 200. The engine and dynamo are stationed in a shed about 180 yards distant from the point where the overhead cables enter the house; in this shed, also, is the saw-table, so that by removing the belt from the dynamo and substituting one to the countershaft of the saw the latter can be driven by the engine when it is not required for lighting. The dynamo is driven direct from the fly-wheel of the engine by a 4-inch linked leather belt, which suits the purpose very well, there being no uneven places caused by lacing or other joint to cause any unsteadiness in the running of the dynamo. Owing to the centres of the dynamo-pulley and fly-wheel shaft being necessarily somewhat close together, the belt has to be kept rather tight when required to transmit the whole power of the engine. This, however, has never yet been required, except for experimental purposes. The current generated is led from the dynamo to a set of switches, by which it can be distributed into five separate circuits. The first of these is the circuit exciting the field-magnets of the dynamo itself. The second circuit furnishes lights for the engine shed and the carpenter's shop adjoining. The third goes to a school-house near. The fourth goes, by an overhead cable, to the house, a branch being taken off to light the stables. The fifth circuit goes to a board, on which are fixed 100 lamps for experimental purposes; and this circuit is also intended to furnish current to secondary batteries, or accumulators, which the author hopes to introduce before very long The switches distributing these currents are two-way, so that the current can either be sent out direct or can be passed previously through one of Ayrton & Perry's spring ammeters, whereby the amount of current in use on any one or more of these circuits can at any time be ascertained without causing any interruption in the light. The ammeter in use, being constructed to register up to only 20 ampères, has been provided with two shunts of thick german silver wire, so that by using one or other of these the reading on the ammeter is reduced to one-half or one-third of the total amount passing; in this way the total current of 60 ampères can be registered. The current for use in the house is led from the dynamo room to the roof in an insulated cable of fourteen No. 16 wires (0·065 inch thick), and is thence taken overhead through a bare cable of the same size, suspended on poles, to the point at which it enters the house, where it is connected to a larger cable

1. Read before the Institution of Mechanical Engineers, Lincoln, England, August 4.

Digitized by Google

of nineteen No. 14 wires (0.085 inch). This cable has been provided in order to admit of a larger number of lamps being used in the house at some future time without disturbing the wiring, &c., inside the house. It leads well into the middle of the house, giving off on its way smaller branches to light sections of rooms, and then connects to a smaller cable, which again is reduced to a still smaller one before reaching the far end of the house. These cables all give off smaller branches to light the various rooms both up and down stairs. At their junctions with the mains the branches are fitted with fusible cut-outs, so that, in the event of any short circuit occurring of sufficient magnitude to cause any undue heating of the branch, the fusible plug would go, and would cut off that section. Most of the switches used have also fusible plugs in them, and are of the quick-breaking type, so that they cannot be left in such a position as to form an arc. The lamps used are mostly 100 volt 20 c.p. lamps of the Edison and Swan make, but in some cases two 50 volt 10 candle lamps placed in series are used, instead of one 20 candle lamp. This is principally the case in passages, which are thus better lighted by the greater diffusion of the light, and, moreover, it is never required to light one of these lamps without the other. In the chapel there is a hanging chandelier with 20 lamps, in which the current is conveyed to the lamps by the suspending wires, and the chandelier is so arranged that, for the purpose of replacing lamps which have failed, it can be raised or lowered without disturbing any connections. In most other cases the lamps have either been left simply attached to the ends of the wires or have been fixed to the old gas-brackets. In the author's private workshop are a few lamps attached to flexible wires, which are very convenient for placing in various positions for working, and especially for turning. The installation was first used in November last, and everything worked very satisfactorily, with the exception of the governor, which proved utterly unsuitable, the inertia being so great that its position would remain the same for a very considerable variation of speed; so much so that, although an adjustable resistance of considerable magnitude had been inserted in the circuit exciting the field-magnets of the dynamo, it was found impossible, even with this, to control the electromotive force to the point required. Frequently when resistance was inserted, thereby lessening the work done by the dynamo, the engine, in consequence of the lightened load, would increase its speed sufficiently to bring up the electromotive force to its old point. The consequence was that it was necessary to keep the steam pressure in the boiler almost absolutely constant, or rather, to allow it so to vary in proportion to the load that it should keep the electromotive force constant. This was found exceedingly difficult in practice, and it was soon seen that it would be necessary to get some more efficient kind of governor. Having seen the working of Mr. Richardson's electrical regulator, and being much pleased with its principle of action and with its performance, the author decided to try it, and one was accordingly adapted to his engine. Although this old-fashioned type of engine does not lend itself very readily to the introduction of the necessary valve, the object was attained in a very efficient though possibly rather unsightly manner, by taking the steam from the top of the safety-valve fitting and passing it through the throttle-valve actuated by the governor, and thence downwards into the steam chest. The regulating part of this governor consists of a double solenoid magnet, placed vertically, and wound with insulated copper wire, within which works a double core, and to the cross-piece at the bottom of the cores is linked the long arm of a lever, the short arm of which presses upon the spindle of a double-beat Cornish valve that controls the admission of the steam to the steam chest. For incandescent lighting in parallel, the wire, on bobbins, is placed in shunt circuit between the main leads, and the size of wire used is adjusted according to the electromotive force which it is desired to maintain between the mains, so that when the electromotive force is at the right point the cores are suspended within the solenoids by their attraction. Inasmuch as the resistance of the solenoids is fixed, any increase in electromotive force causes an increased current to flow through them, whereby the cores are immediately attracted with an increased force, and are caused to move upwards, thereby acting through the lever to close the valve until the electromotive force has been brought down again to its normal amount. The required movement of the valve is exceedingly small, and this method appears to be the best suited for electric lighting. An automatic expansion gear, on which the governor might be caused to act, has the disadvantage that, when but few lights are burning, the steam is cut off at so early a period of the stroke that unless the fly-wheel is exceedingly heavy a fluctuation occurs in the light during each revolution of the fly-wheel, somewhat analogous, though, of course, in a much smaller degree, to the unpleasant bobbing generally seen in electric lights driven by a gas engine where there are no accumulators. In a large engine, where economy of coal has to be considered, probably the best way would be to have an expansion gear actuated by hand, which can be set approximately to the expansion required, leaving the throttle valve to regulate the speed finally. But where perfect steadiness is desired it is probably better not to cut off much before half-stroke, especially if a single-cylinder engine is used. The use of accumulators as regulators would, of course, prevent a great deal of the fluctuation, and would permit of the steam being cut off much earlier without causing any apparent unsteadiness in the light. The electric governor was fixed on the engine, and worked for the first time on January 13 last. The improvement was remarkable, the lights remaining steady without the sudden alternations of brightness and dullness which had occurred before. But it was still found that with any considerable variation of boiler pressure or of load the electromotive force in the mains varied more than was thought conducive to long life in the lamps. As, however, it was found that, by augmenting or diminishing the weight suspended from the core bars, the electromotive force could be brought back to its normal amount, it occurred to the author to fix an upright cylinder in direct communication with the boiler, and to make its piston rod press upwards on the core bars, the diameter of the cylinder being experimentally determined by observing the weight necessary to be added or removed for certain variations in boiler pressure. This arrangement caused a very great improvement; and when the load was approximately the same it maintained the electromotive force constant under very considerable variation of steam pressure. When, however, the load was varied very considerably, say from 1 lamp to 100, it was found that more variation took place in the electromotive force than was desirable. The arrangement was accordingly modified by causing the piston rod to act upon a lever, and by introducing a second cylinder supplied with steam from the steam chest, the second piston rod acting upon the same lever, but upon the other side of the fulcrum. The end of the lever was furnished with a steel knife-edge, bearing against another knife-edge set at right angles to it upon the prolongation of the core bars. The cylinders were also both of them made larger, and were placed so that they could either of them be moved nearer to or further from the fulcrum of the lever, whereby the resultant effect of their differential power could be easily adjusted. This arrangement answered very well indeed, and it was found that the lights could be varied from 1 to 100, and the boiler pressure from 30 lbs. to 60 lbs., with but very slight variation of electromotive force in the mains, provided, of course, there was sufficient steam to do the work required. It is also quite easy to cause the electromotive force to rise as the load on the engine increases—or, in other words, as more currents pass through the main—by simply giving greater leverage to the piston connected with the steam chest. In fact, with this arrangement, the

Digitized by Google

electromotive force can be maintained practically constant, or can be made to vary in any desired manner with variations of steam pressure or of load. The main leads to the house having a resistance of about 0·2 ohm, there is a loss of about 12 volts of electromotive force when 60 ampères of current are passing along them between the terminals of the dynamo and the house; whereas when only one or two ampères are passing the loss is practically *nil*. Hence if the electromotive force were maintained constant in the dynamo-room, it would fall at the house as more lights are turned on. In the case of an engine controlled by an isochronous governor this difficulty is supposed to be met by the compound winding of the dynamo machine. There are, however, several disadvantages in that plan. One is that each dynamo ought to be specially wound for the electromotive force desired to be maintained, and for the external resistance between the lighting centre and the dynamo; and if either the electromotive force of lamps used or the external resistance is varied, the adjustment of the machine is destroyed. This also in a great measure prevents the use of reserve machines for a large installation where several circuits are used, because the reserve machines cannot suit all the circuits equally. Another disadvantage in a compound machine is that, if it be used in conjunction with secondary batteries, and the engine be permitted to slow down before the connection between the dynamo and the batteries is broken, the current from these last will flow back through the dynamo, and will reverse the polarity of the magnets if it be a compound machine; and when next started, the batteries and dynamo will be wrongly connected, and considerable harm may ensue both to batteries and to dynamo.

The plain shunt-wound machine is free from these objections; but the disadvantage has hitherto been that as more lights were put on the electromotive force fell just when it should rise. With an electrical governor this can be obviated, as indicated above, by a suitable arrangement of the piston actuated by the steam from the steam chest. But a still better plan is probably that adopted by the author, of taking certain points as lighting-centres, and keeping the electromotive force between them constant. For this purpose small wires are connected with the mains at the required points, and the current to actuate the governor is taken off there, instead of direct from the terminals of the dynamo. One of the points is just outside the house, where the wires enter; and the other point is in a room. The electromotive force between one cable and the other cable is maintained constant by the governor. This arrangement could easily be applied to a large installation for a town, each engine and dynamo having its particular district. The cables would be led direct to the district, and governor wires would be led back from the district to the engine governor. The arrangement of splitting up the required power into several small engines, instead of employing only one or two very large engines, permits of this plan; and also requires very much less reserve of power to provide against a break-down. For example, if the lighting of a town be estimated to require 2,000 i. h. p., and this be divided between two engines of 1,000 i.h.p. each, it will be necessary to have either one or two similar large engines in reserve, according as it is intended to provide against a single or double break-down. If, however, the same power be divided amongst 40 engines of 50 i. h. p. each, it will only be necessary to have a reserve of one or two of these smaller engines for providing against similar contingencies. A simple arrangement of switches would then at once permit of a reserve engine with its regulator being switched on to any particular circuit on which it might be required, owing either to a temporary break-down or to a special extra demand for current. Another advantage of an electrical governor over any arrangement of isochronous governor, however perfect, is that the electrical regulator takes its regulation from the mains, and not from the engine; consequently, if there be any loss, either by slip of belt, or by extra heat in the field-magnet circuit or the armature, causing increased resistance, this will be compensated by the electrical governor at once driving the engine so much faster as to make up for it. On one occasion when experimenting with the governor, this was specially noticeable; for when the load got rather heavy, the belt at the time being rather too slack, the engine suddenly increased its speed considerably, but the voltmeter remained at the same point, and the dynamo was found to be running at just about its ordinary speed, the extra speed of the engine being evidently caused by slip of belt. When the lever arrangement was completed, several experiments were made by Mr. Richardson and the author, the results of which were as follows. When the load on the engine was allowed to remain constant, with only one lamp alight, it was found that while the steam pressure was allowed to vary between 31 lbs. and 55 lbs. the electromotive remained constant at 90 volts. Afterwards, with the same extent of variation in steam pressure, and with the load also varying from 1 lamp to 91 lamps, the electromotive force varied only two volts, namely from 91 volts to 93 volts. The following are the particulars of this second set of trials:—

Steam Pressure.	Number of Lamps.	Electromotive Force.	Steam Pressure.	Number of Lamps.	Electromotive Force.
Lbs.		Volts.	Lbs.		Volts.
55	1	92	45	61	92
55	11	91	35	50	92
55	21	91	32	41	93
55	31	91	32	31	93
55	41	92	32	30	92
55	51	93	30	71	92
55	61	92½	35	91	92
55	71	92	40	91	93
55	81	92	45	91	93
55	91	92	50	91	92½
50	91	92	50	91	92

The arrangement of the governor has since been modified, in order to obtain a neater-looking arrangement and also better results. Here there is also the advantage that, if an ordinary centrifugal governor be added to the engine —which may be done as a measure of safety, in view of a wire breaking or of the main driving belt coming off; and which must be done if the engine be required to do other work, such as sawing or pumping, at times when the dynamo is not running—the throttle valve will still be compensated by the lever, which would not be the case if the compensating arrangement were attached only to the solenoid. A specimen of the combined electrical and centrifugal governor is exhibited. When the cores of the solenoid are in the most favorable position, the difference of pull caused by a small movement of them is very slight; and the movement required to open or close the valve is very small. Through a valve similar to the one shown, steam sufficient to indicate 55 h. p. has been passed with a lift of only 0·1 inch, and with a difference of less than 5 lbs. between the pressure in the boiler and in the steam chest. When it is desired to vary the electromotive force in the mains, a set of adjustable resistance coils is inserted in the governor circuit; by increasing these resistances, a higher electromotive force is required to drive the normal current through the solenoid, and thus to close the valve. In this way the speed of the engine and the electromotive force in the main wires may be varied to almost any required extent, and from a point however distant from the engine. The author has one set of these coils fixed in the circuit in the dynamo room, and another in the house; and by moving either of these the resistance may be increased or diminished, producing a corresponding variation in the electromotive force. This is found a great convenience when exceedingly exact electromotive forces are required for experimental work, which sometimes cannot be carried on in the immediate neighborhood of the dynamo machine. It may also be arranged practically to dispense with the necessity of any telegraph or signal to the engine room,

Digitized by Google

because a switch and set of coils placed in any convenient position afford the means of varying the light as desired, without any reference to the engine driver, whose work then consists simply in seeing that sufficient steam and water are maintained in the boiler, and that all bearings are kept duly oiled. In the case also of an engine doing any other work, where it is desired to vary its speed from a distance, the same governing arrangement may be applied by causing the engine to drive a small dynamo just sufficient to furnish electricity for the electrical regulator. The electromotive force in the mains would then furnish at any desired point an indication of the speed of the engine at any moment; and a switch and set of resistance coils would afford the means of altering the speed to any other desired rate. As the amount of current required for driving the regulator is only small, the coils and switch may be made very small and compact; so that in a theatre, for example, they might be placed in the prompter's box, and the whole system would then be under his immediate control. The introduction of this governor has, in the author's opinion, contributed very largely to the duration of the lamps used. From the first start until the end of last year the time of running was 370 hours; and during that time with the old governor five lamps gave out, although they were all new when the installation was started; the average current during that time was 16 ampères Up to January 13 last, when the new governor was first introduced, the time of running was 477 hours, and 13 lamps had given out; probably also many of the others had been damaged. Nevertheless during the 487 hours running in February, March, and April, although the average current used had increased owing to the extension of the installation, only ten lamps gave out; and during the 84 hours running in June only two lamps gave out. Hence it appears that a good governor will soon save its own cost by an increased life for the lamps. Thus far reference has been made solely to incandescent lighting in parallel; but for arc lighting in series the advantages of a governor of this description are very conspicuous. Probably the best system of driving arc lights in series is by the use of a series-wound dynamo, especially if a compound engine be used for the purpose, because then the steam-chest pressure remains approximately constant, and the speed varies approximately in accordance with the number of lamps in use. Here an isochronous governor is obviously altogether useless. An electrical governor, however, meets the case perfectly. Here the whole of the current to the lamps is led round the solenoids, which are, of course, made with fewer coils of a thicker wire. When any lamps are short-circuited, a momentary increase of current takes place, which instantly raises the cores in the solenoids, and shuts off the steam, reducing the engine to the required speed for the number of lamps left on. The following are particulars of some experiments made in 1883 by Professor Thompson, University College, Bristol, with a machine of this description :—

Lamps Alight.	Ampères of Current.
0	10·6 to 11·2
5	10·0 10·5
11	10·0 10·3
16	9·9 10·2
17	10·1 10·2

Before the introduction of this regulator very considerable trouble was experienced in keeping the speed at the proper point, and many of the fine-wire coils of the Brush lamps were destroyed by an excess of current going through the circuit. Now, however, the current has been effectually controlled, and any number of lamps can be switched in or out without any attention being paid to the engine. Here also an arrangement is introduced by which, should the main lead become accidentally severed, the engine is at once stopped. A small electro-magnet is introduced, round which the current is led with a few turns of wire. The magnet supports a weight of several pounds, which is attached to a lever so pivoted that, when on the cessation of the current the weight falls, the lever presses with great force on the top of the valve-spindle, and shuts off the steam altogether.

PLACING WIRES UNDERGROUND.[1]

There is no more important question before the electrical community of this city to-day, than the underground line problem. Every branch of business requiring the use of pole lines must shortly be brought face to face with its actual solution. While there may be a difference of opinion as to the authority of the state to compel the abandonment and practical destruction of the overhead plants which actually exist, and which have been constructed in accordance with the requirements of the proper authority, there can be little doubt that the building of a new aerial street line in the future may and probably will be absolutely prohibited in the cities of New York and Brooklyn.

As an instance of the present state of affairs I will call your attention to the dilemma in which the United States Illuminating Co. finds itself to-day. This corporation shares the business of electric lighting for streets with the Brush company in this city. Owing to the enlargement of the Grand Central depot, at 42d street, and the opening of Depew avenue, it was found necessary to abandon the 44th street station. A new station was equipped at the foot of 29th street, East River, to which the lighting circuits were to be led when the machinery was in readiness. This change required the construction of a new 50-wire line through 29th street, a distance of 3,600 feet. Upon application to the Commission on Electric Subways, a permit for this purpose was refused. I was informed by president Lynch that they would soon be turned out of their old station, that their customers could not be supplied from their other stations, and that nothing remained but for the Commission to provide a method by which they could comply with the law.

I narrate this incident merely to point out to you the conditions existing here to-day. To show also that overhead construction is not entirely prohibited, I will read you the following item from the *Evening Telegram*, of August 19th :

MORE TELEGRAPH POLES.

Gangs of workmen invaded West 28th street this week and erected telegraph poles along both sides of the street, against the protests of the residents, who claim that according to the law recently passed the telegraph companies have no right to erect any new poles, and must put the wires underground.

The members of this association being chiefly interested in arc lighting outside of the territory embraced in the Daly underground bill, this subject is not in every case one of immediate importance. It is not at all improbable, however, that other and smaller cities may enforce similar legislation, therefore it will be wise for you to consider the whole matter very carefully.

As you are, of course aware, the burying of the existing wires in New York is a complicated engineering problem. Not only are there thousands of wires owned by various companies and individuals, but the different systems require different subterranean facilities. Curiously enough the thunderbolts of the press have been hurled with the greatest force against the Western Union Telegraph Co. for its apparent calmness in ignoring the requirements of the law. As a matter of fact this company began placing wires underground about ten years ago, and employed an engineer for the express purpose of preparing plans for a general system, which was to include at least the Western Union, Metropolitan Telephone, Gold and Stock and American District Telegraph companies. I understand this work had to be abandoned mainly because of the destruction of the gutta-percha insulation by the effects of the

1. Read by Ralph W. Pope before the National Electric Light Association, New York, August 20th, 1885.

Digitized by Google

steam heating pipes. The system adopted was that used in England—the simple drawing of gutta-percha cables through ordinary cast iron pipes. A similar plan was recently put in practice by the Commercial Cable, popularly known as the Mackay-Bennett Cable Co. In the upper part of the city, however, the cable is simply buried in the earth, being protected by a line of blue-stone flagging on the surface.

The Edison incandescent system, as you are doubtless aware, is entirely underground, and is too well-known to require attention at my hands. It was planned with a view to the requirements of the Edison company, but is apparently not suitable for all branches of the electrical service so far as has yet been demonstrated.

I am not aware that any arc lamp wires have as yet been placed underground in this city, neither have I learned of any plan by which they were to be so treated. I consider this the most difficult part of the work, and the most expensive, on account of the large wires required, and the necessarily high potential of the currents used. In reply to the question: "Is this feasible?" I say yes, it must be. It may be an expensive method, and more serious objections may arise in practice than we anticipate, but it is foolish to regard it as an impossibility, in this day of great engineering achievements. Its success requires plenty of dollars and plenty of sense. Furthermore, if arc lighting is to increase in this city it must be done, as no franchises for further aerial construction will be granted. As this crisis was bound to come, I think it was well timed, for the reason that reconstruction of the lines in this city would soon be necessary under any circumstances, and if lines must be abandoned it is less wasteful to destroy those already depreciated in value and which should have earned their cost, rather than those which are in good condition. The lines of the electric lighting companies in New York are not of a permanent character. The poles are slender, and the fibrous covering with which the wires are supposed to be insulated may be seen hanging in threads from the weather beaten structures, as you pass along the streets. I don't know how long it was expected that these lines would endure, but they are apparently not long lived. The cost of placing them underground is an expense which I presume our lighting companies are at present scarcely prepared to assume. It will naturally vary in different localities and under given conditions.

In the absence of any plans presented by the companies, the New York Commissioners will devise means by which conduits or subways will be prepared with facilities for accommodating the wires of all companies. It is to be presumed that they will then notify all interested parties that by lease or purchase they may obtain perpetual rights in such subways to place their wires. No system will be approved which is not sufficiently comprehensive to meet the demand for all classes of service.

This leads to the question as to what plan is the best, and this must be finally decided by the Commissioners after examination of the various schemes presented, and their name is legion. I will not occupy your time by even calling your attention to the various theoretical devices presented, of which I understand there are over 250, as most of them can never be of any practical value, while but very few are in actual operation.

Of conduits which have been really used for this purpose, and have, therefore, been tested by experience, but two have been brought to my notice. These are the conduits which have been put down to some extent in Philadelphia and Chicago. The latter is known as the Dorsett underground conduit, and has been used in Chicago for over a year. The same material has, however, been in use underground in the form of sewer pipes for six or seven years without apparent disintegration. A conduit used in Philadelphia was troubled some time ago by explosions which arose from the accumulation of gas in the manholes. This was supposed to have been caused by leakage from the gas mains. While in Philadelphia last year I saw a line of arc lamps which I believe were supplied from wires through this conduit. With a little more time at my disposal I should have been glad to have looked into its details more thoroughly.

The conduit, as used in Chicago, appears worthy of attention, as being the most successful system of this class which has thus far stood the test of experience, and may now be seen in actual operation, occupied by telephone, telegraph, and electric light wires. It is made of concrete, formed by mixing asphaltum and silex, and is moulded and at the same time hammered into lengths of three feet, through which are formed at the same time longitudinal ducts, the whole having the general appearance of a tubular boiler. One end is provided with a flange, so that the sections may be securely joined, when they are cemented with the same material applied while hot, and a perfectly tight joint formed. At the corners of the streets manholes are provided, formed by the same material. These like the conduit itself are gas, sewage and water-proof. The material is said to have stood a government test of 5,500 pounds, crushing strain per cubic inch. It is also a practically perfect insulator; and the ducts are smooth and uniform inside, being about two inches in diameter. Mr. Callender informs me that he has drawn several miles of cable into them without any apparent damage from abrasion. This system was adopted over a year ago for the municipal wires in Chicago, and also by the Underground Conduit Co., of which Professor Elisha Gray is president.

A recent experiment, which will perhaps be of interest to you, appears to have fully demonstrated the insulating properties of the concrete, which being cheap may possibly be practically utilized in this novel manner. The test which was but an experiment, consisted in placing naked wires in one of these underground conduits for carrying electric light currents. The plant of 40 lights is still running successfully. While this proves conclusively that such wires may be safely run in the manner indicated, it was not intended to continue the arrangement permanently. The installation of the wires spoken of where they are liable to dampness or other interference at the terminals of the pipe, was very complete, and the insulation rendered very thorough, by the following process, which is given for the benefit of those interested: The wire, before drawing in, was thoroughly taped from the union between the naked copper and the outside wire, for a few inches at either conduit terminal into the pipe. A cork, slit to receive the wire, was then placed upon this latter, and crowded into the end of the conduit about an inch. Then this countersunk space was filled with the compound which completely insulated the wire at the terminals of the tube, and made these air, water and gas tight, at the same time. As some of the members present may have occasion to visit Chicago, I would suggest that it might be worth their while to satisfy themselves of the merits of this conduit, as can of course be done most effectually by examination and inquiry on the spot.

Whatever conduit may be used the individual insulation of wires is essential. The tests which have been made thus far with insulation for arc lamp wires under these conditions are exceedingly meagre. A series of tests are now being made by the Standard Underground Cable Co., of Pittsburg, which will doubtless be of value in this respect.

It is a peculiar trait of human nature that we prefer to profit by our own experience, rather than abide by the testimony of others. I would therefore respectfully suggest that such members as can do so, should after careful consideration of the subject undertake the construction of short experimental underground lines with a view not only to preparation for the future, but to ascertain for the benefit of the entire fraternity the best insulating material for subterranean arc wires. In cases where antagonistic legislation is threatened, the very fact that you are laboring in that

Digitized by Google

direction may prevent your being forced to do so, hastily and against your will.

The burying of the wires in New York is a work of great magnitude, and should properly have been begun many years ago in order that we might have thoroughly learned our trade instead of undertaking so vast a job as mere apprentices in underground work.

My brief intercourse with the Commissioners leads me to believe that they fully realize the importance of performing the duty which has been placed upon them, with a proper regard for the continuance of all classes of service without interruption. When the task is finally completed, and the wires working satisfactorily, with bills all paid, and dividends appearing regularly and frequently, we may be happier—I am sure we shall be older.

THE DURABILITY OF DYNAMOS.

The subject of the life of a dynamo for electric lighting purposes, has been frequently brought to our attention by many who are anxious to see the electric light at their mills or works, but have been deterred from incurring the expense of an installation by the absurdly incorrect statements made, and often accepted, relative to the durability of a dynamo. Its life has been variously given at two years and upwards, an estimate so low as to be sufficiently absurd. If a dynamo be cursorily examined, it will be seen that the elements of "wear and tear" are but small. The field-magnets and pole-pieces of solid iron, carefully wound with layers of well insulated wire, present nothing for deterioration. The properly-constructed, well-fitted "armature" should last without fear of damage, with the exception of such parts as are liable to friction. In the bearings themselves, if properly lubricated, there can be no wear more than in any ordinary engine bearing, but it is in the "commutator" and the collecting "brushes" that "wear" must go on. We have here the copper brushes pressing against the copper bars of the armature commutator revolving at various speeds, and it is here, where there is a certain amount of friction, that there must not only be a certain loss of material in the brushes, but also in the commutator bars. This loss is certain and definitely small with a good dynamo and one carefully attended to, but with inferior dynamos and loose attention, when "sparking" occurs the brushes are soon worn down, and the bars getting "scored" sooner require being "turned" to get a smooth surface. The sparking of a dynamo must sooner or later ruin a commutator (but it is a considerable advantage to know that you possess a machine whose commutator can be easily replaced), as every spark means more or less metal destroyed.

In a paper recently read on "Electric Lighting for Steamships," it was mentioned that the dynamos on the "Himalaya" had an exciter of the Siemens type. It had been running constantly for two years, and had not had any repairs done to the commutator, which might be considered very good wear. Although this question is one of great interest as affecting the "maintenance" of an electric light installation it was not again referred to, but in a recent number of our contemporary, the *Electrical Review*, particulars are given by Mr. Ernest Berry of the first year's cost of the installation at the Prince's Theatre, London, and he remarks that the Siemens dynamo "is in as good condition as when it was first put down, with the exception of the wear on commutator (which, on being measured after 12 months' wear, was found to be $\frac{1}{16}$ths of an inch). The machine has used in that time 5½ pairs of brushes four inches wide." From the number of dynamos we have seen at various times, we should consider that in this case the "depreciation" of the dynamo and the cost of maintenance above the average. It was only a short time before this case met our attention that we carefully examined a dynamo, which was also used for a theatrical installation, in order to see what the loss had been on the commutator. It was a 250-light Edison machine, and had been constantly running for nearly 2½ years, and from the feel of the hand over the commutator, it was almost impossible to perceive that there was any wear. Applying a straight-edge, it was possible to perceive that the surface had been reduced to the extent of the thickness of a piece of writing paper. As regards the brushes, these were the same as originally fixed, and would still last for a longer period. In this machine (running at 820 revolutions per minute) sparking was never observed; the same may be said of the other Edison machines of the same type belonging to the same installation.

The wear and tear of this dynamo was practically almost *nil*, and granted that it received in the future the same attention it has had in the past, it would be almost impossible to fix the limit when the occasion would have arrived to replace the commutator with a new one. The average life of a dynamo may, therefore, be considered to be at a high figure, provided that due care be taken of the adjustment of the brushes; and its cost of maintenance as that of an occasional pair of brushes, and the removal of the commutator, the cost of which would have to be spread over a number of years.—*Mechanical World.*

HOW MACHINERY IS RUINED.

We have again beheld the results of "smart Aleck" engineers, those $10 per week men, who are expected to attend to their employers' horses, sweep up the shop, and what spare time they have attend to their boilers and engines. During the past week we were in one of the southern cities. The elegant hotel where we picked our teeth was lighted by electricity. One day the "thing" (I cannot bring myself down so low as to disgrace my loved profession by calling him an engineer) had keyed up his engine without letting the electrician know of it. About an hour after it started, somehow it got tired and stopped. Imagine the effect—house in mourning. Had melted linings of brasses; electrician mad; saw us and asked assistance; given; brasses changed in a few moments; engine started; enjoyed an evening with electrician; were chums eighteen years ago on a western railroad; expressed our mind plainly regarding "thing;" no good; employer believes that if a man can throw coal he is as good as can be. We have seen engineers around hotels who were porters and wood sawyers, and the only wonder is that we don't hear of more "Galveston" accidents. For "Contented's" benefit, allow us to inform him that we are not tramping in search of employment. We chose that cognomen because our work calls us all over the country, and because we are so situated as to be directly opposite the tramp. From that hypothesis we argue that he sails under the "contented" flag, because he is "uncontented."

—*Boston Journal of Commerce.* Tramp.

GIMLET-POINTED SCREWS OF 1755.

Mechanics of adult age can easily remember when gimlet-pointed screws came into use within the last 30 years, superseding the blunt pointed ones before used, and the former have been considered a modern invention. But we have lately seen half a dozen screws with excellent gimlet points, which were taken from an old piano, and bear unmistakeable evidences of age, and of having been made before screws were made by machinery. The piano is inscribed "Jacobus Kirckman, Fecit, Londini, 1755," and the screws are doubtless of that date. The most curious point in the case is that after such screws as these had been once made mechanics should have gone on using square-pointed screws for nearly a century.—Worcester, Mass., *Gazette.*

THE CONSTRUCTION OF LINES FOR ELECTRIC CIRCUITS.

BY THOMAS D. LOCKWOOD.

(Continued from page 298.)

LEADING WIRES INTO OFFICES OR BUILDINGS.

It is said that there is a right way and a wrong way to do everything. It may be stated with equal truth that there are many right ways and many wrong ways to conduct wires into buildings, and it is one of the most characteristic marks of a first-class constructor that he suits his style of entering, and indeed all branches of his work, to the particular circumstances and conditions which he may find at any special time and place. Hence, it is hardly right or fair to say "Such a way is the proper way to do this" or "This only is the correct method of accomplishing what is required to be done." Take for example the following case. The main line is supported on poles and runs past the front of the building in which as a way office the wires are to be run. If a pole happens to be exactly in front of the office, it is only necessary to run the line wires direct from the insulator, into the building through hard-rubber tubes which are fitted into holes passing through the upper crossbar of the window frame, and when the wire ends are inside, they can be twisted up so as to prevent their egress, the inside wire being then attached to the twisted ends. If the pole is not opposite the building, a small terminal pole may be set there, or brackets and insulators may be fastened near the window, and the line from the nearest pole on each side run direct to the window insulator. This is one way —I do not, however, regard it as being the best.

If several wires are to be run in at a window, a good plan is to fix a heavy pine crossbar having the required number of hook insulators screwed into its beveled corner, over the outside of the window and to terminate all the wires thereon, by first twisting them round the hook, and then winding them back on themselves, or fastening them with binding wire. Stout copper wire, heavily insulated with rubber or kerite, is then passed through the window frame to connect with the inside wires, and after stripping about 14 inches of the ends of the insulated wires, and brightening about four inches of the line wire, the copper wire is wound closely round the latter, thus making the connection; the winding in all such cases requires to be begun at the point nearest the insulator and to progress outwardly. It is quite necessary that all connections made as above between the iron and copper wires be soldered as with other splices. They should, however, only be soldered at the outer end of the winding so that the end only, of the copper wire is homogeneously attached. The reason for this is that it sometimes becomes necessary to unwind the connection for testing purposes, which could not be done were the soldering to extend from end to end.

There is still another way of bringing the main line to the window which sometimes must perforce be adopted. It occasionally happens, that wires have to be run from the main line into the front of a building while the owner of the building will not permit any fixture, no matter how small, to be attached.

The only way in such cases, is to divide the wire as it runs past the building, and to insert an insulating substance between the divided ends. An ordinary glass insulator with the closed end punched out, may do, although it is better to have insulators prepared for this work after the style of the English shackle. A short wire may then be spliced to the main line on each side of the insulator and run straight to and through the window frame. These short wires ought to be insulated.

To enter a window from the top of a building, a batten or counterbrace may be fixed to overhang the wall, and the wire led first to a hook insulator attached to it, and dropped plumb, to a second hook in a block, close to the window, from which it may be run in. Whether it is preferable to let the wire run in the window at the top or bottom of the frame must be determined by circumstances.

If the inside wires are to be run near the ceiling the top is best. If on the contrary the objective point is near the floor the bottom is best, as it is an advantage to have as little inside work as possible. If also there are unoccupied holes, already bored in the frame, these should be used rather than make others. If there are no determining circumstances I would recommend the upper part of the frame, as being more out of the way. Wherever wires, no matter how thoroughly insulated, run over and are in contact with brick, stone or ironwork, they should be "cabled," a word which, when used in this connection, simply means wound round at the point of contact with a short piece of rubber-covered or kerite wire, so that not the circuit wire, but the wound wire, will touch the building. Gutta percha covered wire is not adapted for this, or for any open air work, as it oxidizes rapidly and cracks when exposed to the air, unless well covered with tape soaked in wood tar, which should frequently be re-tarred. The better way is not to use it at all. A very neat way to bring wires into a residence is to carry them from hook or insulator, to other hooks down the side wall, and then in through the cellar window frame, when from the cellar they may be run wherever wanted. This is very convenient if testing is afterwards to be done. If wires are to be run into a building from the roof, and it is not convenient to reach a window, a search should be made for well holes or unused flues. When the latter means of ingress is to be used, the wire is or may be guided to its destination by means of a string which is first dropped down with a pebble attached to it.

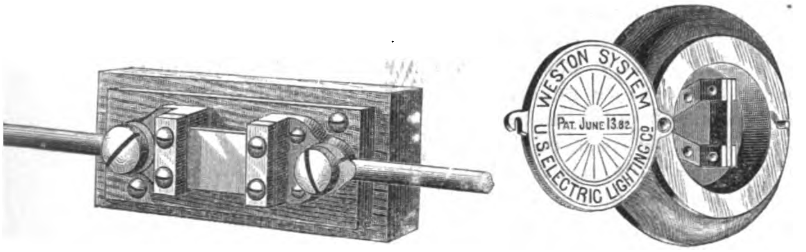
It sometimes occurs with city wires, that a circuit is already looped to a number of windows on the rear or side wall of a building; when this is so, and still another connection is to be made on the same side of the building, instead of dropping an entirely new loop from the roof to the required point, the best way is to make a branch loop from the nearest window already connected; and by so doing much wire can be saved.

Wherever hard-rubber tubes are employed in passing through a window frame, good practice requires that they shall be inclined downward to the outside, to prevent moisture from entering. Each entering wire should also be given, wherever possible, a bend downward between the last block or hook and the window, and the holes through window frames should invariably be bored at an upward angle from the outside, for the same purpose. If many wires have to enter a building, such for example as a telephone central office, a cupola or roof house is usually provided and surrounded by a suitable fixture to which the linewires are first attached, and from whence they are led into the cupola, where after passing the lightning arresters or dischargers they are connected to the office wires.

It is essential in conducting electric light wires into a building that the greatest care must be taken to prevent even the slightest degree of leakage. The New York Board of Fire Underwriters requires that all wires, machines and lamps are to be so mounted and secured as to insure complete and continuous insulation; and that in no case must "ground circuits" be employed, or any portion of the system be allowed to come into conducting connection with the earth through water or gas pipes, or otherwise. This being the case, it is evident that a single accidental earth contact or leak will not produce a very disastrous result, but the real danger is that it might remain unnoticed, and that a second ground connection or escape, would complete the ground circuit and probably be dangerous. Another requirement of the board of underwriters is that "Wherever wires are carried through walls, they must be surrounded by a special insulating tube." A porcelain, or porcelain-lined tube is the best, and like all other entering tubes must incline down towards the outside. The wires where they leave the tube must be heavily wrapped with strong insulating tape.

Digitized by Google

The useful device known as a "safety catch" should invariably be attached to electric light wires when carrying incandescent light currents. These should be applied just outside the building, and a good form is that employed by the U. S. Electric Light Co., which is shown in figures 24 and 25.



FIGURES 24 AND 25.

As clearly indicated in the figures, the "catch" consists in a thin strip of easily fusible alloy held between two metal clamps, and thus constituting a part of the circuit.

If from any cause the strength of current passing over the wires into the building becomes too great, the fusible strip is melted and breaks the circuit. It melts, moreover, at too low a temperature to cause damage from the dropping of the melted material.

Another most essential adjunct of electric wires entering a building is a cut-out switch located near the entrance of the building, but outside. This also is required by the New York Board of Fire Underwriters, in the following language: "Wherever electricity is carried into a building by conductors from an exterior source, a cut-out must be provided at a point as near as possible to the entrance to such building."

It is hardly necessary to describe any such cut-out, since its operation is well understood. It must in every case be affixed to a base of some incombustible material such as soapstone, slate, or very heavy plate glass, and it must certainly be arranged to close the one circuit before it opens the other, so that there will be no danger of forming an arc during its movement. If it becomes expedient from any reason to locate the cut-out inside the building, it should be so arranged that it can be operated from the outside also; it should have an indicating signal attached, visible from both the outside and inside of the building, to denote whether the house wires are in circuit or not; and it is quite indispensable that the action of the instrument be automatic when once started in either direction, as otherwise a person unacquainted with the apparatus might partly turn it, and thus establish an arc at that point. The entering holes should be at least a foot apart.

(*To be continued.*)

ELECTRICAL DEFINITIONS, NOMENCLATURE, AND NOTATION.[1]

WITH the rapid progress that has lately been made in electrical science and its applications, there has sprung up a new and fast-increasing class of practical electricians. These, partly from necessity and partly from well-meant respect, have adopted and applied the old terms and expressions which appeared suitable to their predecessors, as well as coined not a few new ones, until now their vocabulary is in considerable confusion, and, as all must admit, requires sifting and reform.

Nothing is more tantalizing and perplexing than the different modes of expression and symbols used by different authors, and sometimes by the same author, to explain and interpret one and the same thing or result. All this might be avoided if an international system of definitions, nomenclature, and notation was agreed upon and legalized. The rapidity with which the new definitions of the ohm, ampère, and volt (issued and legalized last spring at Paris by the International Congress of Electricians) were universally adopted shows this. These definitions should be still further extended to other electrical units. They should embrace a suitable system of notation, whereby electricians could represent in symbols and letters, terms, expressions, and formulæ of common occurrence, in a similar manner to that adopted by chemists in connection with chemical elements and their combinations. Last session the author promised a communication to the society on this subject, and, being again reminded by the secretary of his unfulfilled promise, he now submits a few of the more apparent instances where ambiguity or want of uniformity exists, with suggestions, in the hope that a discussion may follow, and that a committee of this society may be formed to consider and draw up a series of definitions, nomenclature, and notation that would be generally acceptable. The proposed committee might then confer with the French committee, also with a similar committee appointed by the British Association, and finally this important question should be referred to the International Congress of Electricians, in order that they may legalize and issue their decisions in a similar manner to that adopted by them in the case of the ohm, the ampère, and the volt. Undoubtedly, if such a course were adopted, most beneficial results would accrue to all concerned.

Only last November M. Hospitalier brought this subject prominently before the International Society of Electricians at Paris, and strongly advocated an investigation, so that you will no doubt have their support and concurrence.[2]

"Sur la proposition du Président, l'assemblée décide qu'une Commission spéciale sera nommée à l'effet de rechercher les meilleures méthodes à adopter pour les notations électriques et de codifier ces notations.

"M. le Président propose, au nom du Bureau, d'appeler à faire partie de la Commission des notations électriques.

"MM. Ed. Becquerel.	MM. H. Becquerel.

M. V. Williot.

"L'assemblée adopte cette liste à l'unanimité."

Examples.—1. At the very outset students are perplexed by such different terms as "ordinary[3] or static or frictional or high-tension electricity." One author will tell his readers or students: "For a long time the name frictional electricity was given to a group of phenomena produced by electrical changes. This is an improper expression, because friction is only one means for producing electrical changes."[4] Another says: "Static electricity is, however, a misnomer; it has no existence; all the phenomena are due to static strains, but there is always a gradual loss called leakage, which is, however, the current due to the actual conductivity of all circuits, and every motion set up by so-called static electricity implies a transfer of energy and action occurring in a field of force set up in the form of strains in the particular inductive circuit in which the motions occur.[5] A third objects to the word "tension" in respect to electricity, and points out that "all the phenomena observable in connection with so-called high-tension electricity may be produced by electricity

Digitized by Google

drawn from batteries or dynamos, if the electromotive force or difference of potential is sufficiently increased." Would not the term "electrostatics" be more suitable and comprehensive?[6]

2. The old nomenclature, "vitreous" and "resinous," as applied to substances which, when rubbed by certain other substances, produce opposite electrical properties, and the scholastic one and two fluid theories, based upon these effects, should be discarded for the more comprehensive modern theory of electric polarity of molecules or continuous particles, expressed by "positive" and "negative," or by the algebraical signs, + and —.

3. "Electrics," "dielectrics," "non-conductors," "insulators," and "isolators" are terms used by different writers to express a condition or behavior of certain materials with respect to electricity, in contradistinction to the terms "non-electrics" or "conductors," as applied to other materials. The words "electrics," "non-conductors," and "non-electrics" are, strictly speaking, meaningless, because all materials may be termed electrics and all conductors, only differing in degree. The words "isolators" and "isolation" (from the French verb *isoler*, to isolate or separate) should give way to "insulators" and "insulation," as applied to substances which offer a comparatively greater resistance to electricity than semi or good conductors used in connection with the apparatus being referred to at the time.

The term "dielectric"[7] was first used by Faraday on finding that conduction was effected by induction (of polarity from molecule to molecule), and is generally employed by practical electricians when speaking of the inductive capacity of the insulating material surrounding the conductor of leading wires or submarine cables, or that placed between the plates of a condenser. In this sense, viz., of a body transmitting electric induction, or capable of undergoing electric stress, and retaining the stressed condition, it is a very appropriate term to use.

4. The term "accumulator" is the name given in several text-books to apparatus, such as the Leyden jar or condenser, for receiving and retaining quantities of electricity, but has been lately inappropriately applied to secondary batteries, which do not accumulate electricity.

5. "Cascade," as applied to Leyden jars, should give way to "series."

6. "Tension,"[8] "potential," and "electromotive force" are terms which, when variously and indiscriminately applied, have given rise to considerable confusion and a great deal of writing in trying to define them. If we consider "tension" as simply the stress put upon the circuit by the electromotive force, and not in the sense that it used to be employed (for example: "Join up a battery or set of condensers for tension"), it might do very well if kept in its place; but it can easily be dispensed with. "Potential" is a word that has also given great trouble. We find in "Sprague's Electricity"[9] no less than three pages devoted to an explanation of the different ways in which the words "tension" and "potential" are employed. Clerk Maxwell said: "The theory of electro-statics is greatly simplified by the introduction of this new conception of potential." "As soon as we pass from electrostatics to other departments of electrical science, we find that the conception of potential is no longer available, except when used in a restricted sense and under carefully-defined conditions." "In other parts of electrical science we have to deal with electromotive force in cases where 'potential' and consequential 'potential difference' are words without meaning." Professor Fleeming Jenkin, in his well-known text-book on electricity and magnetism, devotes 26 pages to "potential," and defines "unit difference of potential or electromotive force in electrostatic measure to exist between two points when the unit quantity of electricity, in passing from one to the other, will do the unit amount of work." "The property of producing a difference of potential may be said to be due to a peculiar force, to which force the name *electromotive force* is given." "The words *electromotive force* and *difference of potential* are used frequently one for the other, but they are not, strictly speaking, identical." "Electromotive force is the more general term of the two, and includes difference of potential as one of its forms." "Potential" might well be reserved for electrostatics, and "electromotive force" for electro-kinematics, or current electricity, and thus prevent confusion. The word "electric-pressure" has come into vogue lately, and strongly appeals to those of a mechanical turn of mind, seeing that the hydraulic simile of "head" or "pressure" is often brought forward to assist in explaining the terms "potential" and "electromotive force."

7. In magnetism we find the same want of uniformity exists. Take the case of a freely-suspended magnetized needle. The pole which turns towards the geographical north is variously called the "austral pole," "north pole," "north-seeking pole," "marked pole," and is painted red by Sir William Thomson, while Sir Wm. George Airy, Professor Guthrie, and others paint it blue. It is sometimes indicated by French makers by the letter A, and by British by the letter N. The pole which turns towards the geographical south is correspondingly called the "boreal pole," "south pole," "south-seeking pole," "non-marked pole," painted blue by Thomson, and red by Airy, Guthrie, and others, and indicated by the letters B or S. Such is the general doubt and diversity in regard to the nomenclature on this subject, that each author on magnetism considers it necessary to state at the outset which term and symbol he intends to apply. If once for all the pole which turns towards the north was termed the "*north* pole," painted red, and indicated by the letter N, and the opposite pole was termed the "*south* pole," painted blue, and indicated by the letter S, much vexation would be saved. The French terms "austral" and "boreal," with letters A and B, should be obliterated. In this way the earth would have a uniformly recognized polarity, which would of course be opposite to that of the magnetized needle—in other words, the true north pole of the earth would be that situated near the geographical south pole.[10]

8. Sailors and some writers on the mariner's compass call the angle which the magnetic meridian makes with the geographical meridian the "variation" of the compass, while electricians call it the "declination." Variation is, properly speaking, the hourly, diurnal, annual, or secular changes which occur in the value of the elements of terrestrial magnetism. This leads to great confusion and argument between the electricians and the officers of a telegraph steamer. The declination for each place is marked on the Admiralty charts. Sailors also speak of the "deviation" of a compass, meaning by that the local error due to the resultant of the quadrantal, semicircular, and heeling errors. It would be far better if they simply spoke of the "compass error," or angle which the meridian of their compass-needle makes with the true north and south magnetic bearings. This deviation or compass error arises from local magnetic influences on board ship. Sir William Thomson's well-known compass, when properly adjusted on board a ship, has no compass error, and therefore the only thing to guard against and correct for in the steering of a ship is the declination of the place where the ship may be at the time of observation. Of course, if the magnetism of the ship changes in the slightest, due to a change of cargo or position thereof (if of iron or steel), or due to

6. "Electricity and Magnetism," by Clerk Maxwell, Vol. I., Part 1.

7. Faraday's "Experimental Researches," p. 364. "I use the word *dielectric* to express that substance through or across which the electric forces are acting." (See also pp. 537, 538.)

8. For a good definition of these terms, see "Electricity and Magnetism," by Clerk Maxwell, Vol. I., p. 49.

9. 1884, edition, pp. 58-62.

10. Sir W. Thomson calls the magnetic pole of the earth, situated near the geographical north, the "north pole," and the end of the magnetized needle which points towards it the "*true south pole*" of the needle, and paints it red.

Digitized by Google

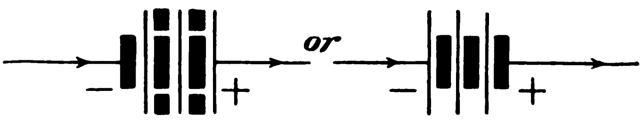
buffeting the waves for some time on one course, a slight error will creep in, but the compass can be soon adjusted to the new condition of affairs, and the officers have therefore seldom to think of or even speak of "deviation" or compass "error."

9. When we come to electricity generated by batteries, we find the expressions "galvanism," "voltaic electricity," "dynamic electricity," "electro-kinetics," "current electricity,"[11] etc., according to the fancy of the writer or speaker. Surely one name might suffice; and certainly the older terms "galvanism" and "voltaic electricity" might well be left to the past. The simple term "current electricity" seems to commend itself, as most of the effects in connection with this branch of the subject have reference to electricity as if it was in motion or distributing itself over a conductor.

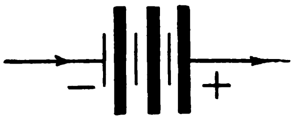
10. "Density of current" and "intensity of current" often cause great confusion. "Density of current" should only be used in the case of electrolysis or electro-deposition of metals. Here it means the ampères per unit of surface of the cathode. In electrostatics "surface density" or "electric density" means the quantity per unit area of surface. "Intensity" was used at one time in the same sense as "electromotive force" is now, and therefore not so much out of place there; but several writers, notably Professor Silvanus Thompson, have thought fit to borrow the French term "*intensité de courant*" wholesale, instead of a translation thereof, and symbolize it by the letter I. The literal translation of the French word *intensité* being strength or amount, therefore the expression "current strength," or simply "current," symbolized by C, is far preferable, for it conveys the correct meaning of the quantity in a given time. With a little pressure, French electricians would no doubt agree to the symbol C instead of I, to promote uniformity. Then I might be reserved for intensity of magnetism, where it suits very well.

11. "Positive electrode" "(+) terminal," "zincode," "anode," "positive pole," and "negative plate," severally used by different writers to designate that end of a cell, battery, or pile where the current leaves, and "negative electrode," "(—) terminal," "platinode," "kathode" or "cathode," "negative pole," "chlorous pole," "positive plate," where the current returns to or enters the same, requires revising and simplifying, more especially when we consider that the end plates of a battery are of opposite sign to their electrodes or terminals, and that the nomenclature is still further complicated when we come to consider secondary batteries or electrolysis by the terms "anion," "kation" or "cation," and "ions. Take, for example, the definition given by Sprague[12] of "anode": "The positive electrode or pole of a battery; the wire or plate connected to the copper or other negative element of the battery; the plate which leads the + current into a solution to be decomposed, and at which are set free the oxygen, acid radicals and all —ions (anions). In electrometallurgy it is usually formed of the metal to be deposited, in which case it is called the soluble anode or pole."[13]

12. Again, we have the two different ways of graphically representing a battery according to the whim or fancy of the writer. Practical submarine electricians were the first



to use this very neat and handy way of representing a battery and its poles, and always adopted the former method with the long thin vertical line for the plate where the current leaves, and the thick short line for the plate where the current returns to the battery. Why should this have been departed from? It is a mere arbitrary arrangement, but, being a most convenient symbol, it should be used in a uniform manner. Mr. John Munro proposes that the symbol for a secondary battery should be a modification of this, viz.:



the current outside the cell proceeding from the long line to the short one.

13. "Parallel circuit," "multiple arc," "loop circuit," "in loop," "derived circuit," "shunt circuit," are all expressions to signify much the same thing, where one expression, "shunt circuit," would do.

14. "Polarization" is a term used in many different senses—for example, the polarization of battery plates, molecular polarization due to electrification or magnetization, polarization of light due to magnetism, etc., as in Dr. Kerr's experiments. Some reform is required here.

15. Coming to telegraphy, telephony, and electric lighting, we find, as M. Hospitalier points out, "the words generator, receiver, transmitter, and motor are mixed up by different inventors, sometimes through ignorance, sometimes willingly." "A generator is an apparatus which, receiving energy of a certain nature, produces an energy of another nature, and it borrows its name from the nature of the energy which it generates. A receiver is an apparatus analagous to the generator, but it borrows its name from the energy which it receives." "A given apparatus is at once a generator and receiver—for example, an electric motor is a generator of mechanical energy and a receiver of electrical energy." "The name transmitter ought to be reserved for an apparatus which, receiving an energy of a certain kind, produces or brings into play an energy of the same kind or of the same form." For example, a relay on a telegraph system, or induction coils as used on a trunk telephone line with several subscribers' lines at each end, or in electric lighting on the Gaulard and Gibbs system, lately tried in London. Professor Silvanus Thompson uses the phrase "dynamo-electric machinery" in the most general etymological sense of the term, as meaning machinery for converting the energy of mechanical motion into the energy of electrical currents, or *vice versâ*, excepting such induction machines as Holtz, Voss, etc. He thinks this reduces the ambiguity to a minimum, and leaves the word "motor" to be applied, if desired, to the steam-engine, water-wheel, etc., from which the mechanical motion is derived. The terms "magneto-electric machine," as applied to a dynamo fitted with permanent field magnets, and "electro-magnetic machine" to a series, separately excited, shunt, or compound-wound dynamo (generator or receiver), are very handy expressions, and should not be discarded.

16. We have dealt hitherto chiefly with definitions and nomenclature, and have given a few examples; others will occur to every member present. We now come to abbreviations and notation with symbols. The want of uniformity here, and the need for systematizing is still more obvious, but perhaps more difficult to accomplish. Every one admits the great advantage in being able to write down the symbols for chemical elements and their actions and reactions one with the other in the form of simple equations, which any one may comprehend who knows the subject, without a detailed description of what each letter or symbol stands for. Electricians should not rest satisfied until they are supplied with a similar universally-accepted notation, whereby electrical phenomena and actions may

11. See Ferguson's "Electricity," second edition, by Professor Blyth, p. 164. The term "electro-kinematics" has been used by Clerk Maxwell to cover a large part of this subject, such as "electric current," "conduction," "resistance," "electromotive force," "electrolysis," etc. (See "Electricity and Magnetism," by Clerk Maxwell, vol. I., part 2.)

12. Sprague's "Electricity," 1884 edition, p. 624.

13. See Faraday's "Experimental Researches," articles 661 to 687, on *Definitions of New Terms*, where he very clearly points out the meaning he attaches to the words "electrode," "anode," "cathode," "ions," "anion," "cation," etc.

Digitized by Google

be similarly treated. The author submits a sample of what he considers would be useful in this respect. Many of them are taken from Munro and Jamieson's "Pocket-book of Electrical Formulæ," where an effort was made to use the same notation and abbreviations throughout, except in such cases as that of quoting direct from some other author.

It will be observed in this list that in most cases the first English or Greek letter of the word has been used. Those relating to the metric system have been copied from the French edition of Hospitalier's "Electrician's Pocket-book," which are no doubt copied from the list decided upon by the international commission on the metre, with a few omissions and additions by the author.

The Greek letters π, μ, ε are universally adopted—π for the ratio of the circumference of a circle to its diameter, μ for the coefficient of friction, and ε for the base of Naperian logarithms.

METRIC ABBREVIATIONS.

m.	for	metre.
cm.	"	centimetre.
mm.	"	millimetre.
m.q.	"	metre-square.
m.c.	"	metre-cube.
c.q.	"	centimetre-square.
c.c.	"	centimetre-cube.
gm.	"	gramme.
mg.	"	milligramme.
k.g.	"	kilogramme.
kgm.	"	kilogrammetre.
&c.		&c.
temp.	"	temperature.
res.	"	resistance.
g.d.	"	gramme-degree.
kg.d.	"	kilogramme-degree.

ELECTRICAL ABBREVIATIONS, NOTATION, AND SYMBOLS.

When a capital letter is used for the symbol, then small capitals or italics with suffixes, 1, 2, 3, &c., may be used for parts making up a whole. For example—L for length, L_1, L_2, L_3, &c., or l_1, l_2, l_3, for different lengths or parts of L.

FUNDAMENTAL AND DERIVED MECHANICAL UNITS.

L	for	Length.
M	"	Mass.
T	"	Time.
V or v	"	Velocity.
A or a	"	Acceleration.
F	"	Force.
δ	"	dyne; *e. g.*, 10 δ = 10 dynes.
W	"	Work.
w	"	weight.
ft. lb.	"	foot pound.
H. P. or HP	"	Horse-power.
I. H. P.	"	Indicated horse-power.
B. H. P.	"	Brake horse-power.

OTHER COMMON SYMBOLS, ALLIED TO MECHANICAL WORK.

S	for	Speed or stress.
D or d	"	Diameter.
r	"	radius.
ω	"	angular velocity = $2\pi n$ in radians per second.
g	"	acceleration due to gravity.
N or n_1 n_2, &c.	"	number of revolutions.
—'	"	second; *e. g.*, $3^{hr}\ 5^{m}\ 10^{s}$ = 3 hours 5 minutes 10 seconds.
$\tau_1 \tau_2 \tau_3$, &c.	"	temperatures, absolute.
or $t_1°t_2°t_3°$, &c.	"	" common.

PRACTICAL ELECTRIC CURRENTS.

The astronomical method of putting the small letters above the line of the figures, as in the case of the example $3^{hr}\ 5^{m}\ 10^{s}$ (3 hours 5 minutes 10 seconds), has not been followed in the following examples, as mathematicians object to the system, the letters appearing as if they were powers. Neither will they readily agree to suffixes, as suffixes have been already adopted by them to distinguish between things of the same kind. The author has therefore written the distinguishing letters on a level with the figures: for example, 10ω stands for 10 ohms (the methods 10^{ω} and 10_{ω} being both objectionable).

C. G. S.	for	centimetre, gramme, second.
R	"	Resistance.
ρ	"	specific resistance.
ω	"	ohm; *e. g.*, 10ω = 10 ohms.
Ω	"	megohm; *e. g.*, 10Ω = 10 megohms.
C	"	Current.
A	"	ampères; *e. g.*, 10A = 10 ampères.
a	"	milliampères; *e. g.*, 10a = 10 milliampères.
E	"	Electromotive force or E. M. F.
v	"	Volts; *e. g.*, 10v = 10 volts.
K	"	Capacity.
σ	"	specific inductive capacity.
Φ	"	farads; *e. g.*, 10Φ = 10 farads.
φ	"	microfarads; *e. g.*, 10φ = 10 microfarads.
Q	"	Quantity (coulombs).
P	"	Power.
W*P*	"	Watts or Watt power.[14]
W	"	Work in Joules.
H	"	Heat in "
J	"	Joule's equivalent = 42×10^6 ergs, or work spent on ·2405 gm. of H_2O raised by 1° cent.

$$C = \frac{E}{R} \text{ (Ohm's law).}$$

$$E \times C = C^2 R = \frac{E^2}{R} = WP \text{ (Watt powers).}$$

$$E\,C\,T = C^2 R T = \frac{E^2 T}{R} = E\,Q = W \text{ (Joules).}$$

$$\frac{E\,C\,T}{J} = \frac{C\,R\,T}{J} = \frac{E^2 T}{J R} = \frac{E\,Q}{J} = \frac{W}{J}$$

$$= W \times \cdot 2405 = \text{g. d. or gramme degrees.}$$

z = Electro-chemical equivalent.

MAGNETISM.

N	for	North pole of a magnet, painted red.
S	"	South " " painted blue.
m	"	magnet strength (of pole) or quantity of magnetism.
l	"	distance between the poles of a magnet.
M or ml	"	moment of a magnet.
$\mathfrak{I}$ or I	"	intensity of magnetization.
s	"	cross section of a magnet.
mp	"	magnetic potential.
μ	"	magnetic permeability.
$\varkappa$	"	magnetic susceptibility.
H	"	horizontal intensity of terrestrial magnetism.
θ	"	angle of deflection.
d_1 d_2 d_3	"	divisions deflection, as in mirror galvanometer.
r	"	radius (mean) of a coil or solenoid.
n	"	number of anything; *e. g.*, turns of wire in a coil of galvanometer.

Take tangent galvanometer formulæ as an example to illustrate the above :

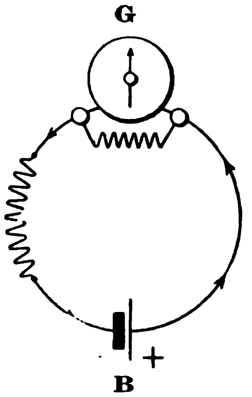
$$\text{Current, } C = H \frac{r}{2\pi n} \cdot \tan\theta$$

14. By adopting the term "Watt power," there can be no doubt what a Watt means.

Digitized by Google

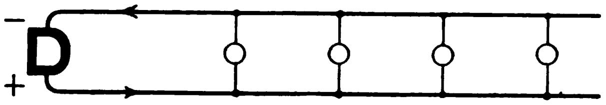
G for Galvanometer or galv. res.
s " shunt res. for galvanometer
r " resistance coils
B " Battery or battery res.

$$\therefore R = B + \frac{G\,S^1}{G+S} + r$$ [15]



DYNAMO CIRCUITS CONTRACTIONS.

Example :



D for Dynamo.
T+ " Terminal positive.
T— " Terminal negative.
E. M. " Electro-magnet.
or F M. " Field magnet.
c. p. " candle-power of a lamp.
A. M. " Ampère-metre.
V. M. " Volt-metre.
S. W. G. " Standard wire gauge.

FOR USE IN FORMULÆ.

R_a R_m R_e for Resistance of armature, magnets, and external circuit respectively.
C_a C_m C_e " Current in armature, magnets, and external circuit respectively.
L_s " coefficient of self-induction.
L_m " coefficient of mutual induction.

In the above notation the first letter of the most important words has been used wherever it was found practicable to do so, and the recurrence of the same letter under similar circumstances avoided as much as possible. In cases where no ambiguity can occur, such as H for the heat in Joules, and H for the horizontal intensity of the terrestrial magnetism; *m* for metre, and *m* for magnetic strength of pole; V for velocity, and v for volts, it will be observed that the same letters appear in each case.

A discussion followed the reading of the above paper, M. Hospitalier, who had come from Paris for the express purpose, leading off with a series of sharp criticisms on Mr. Jamieson's proposals. M. Hospitalier stated that the committee in Paris had already made some progress in devising a scheme of notation and nomenclature such as might form the basis of an international system. Nothing of the kind could be expected of Mr. Jamieson's scheme, which proceeded on no definite principles, and was often contradictory, arbitrary, and hard to remember. Professor Forbes, Professor Aryton, and others followed, their general verdict being unfavorable to Mr. Jamieson's paper. The president, Mr. Spagnoletti, announced that the society had had under its consideration the desirability of arriving at some international understanding on this subject, and had that evening decided to form a committee for its investigation. The committee in the first instance would be a broad one, and not confined to members of the society.

THE CALORIMETRIC MEASUREMENT OF INCANDESCENT LAMPS.[1]

BY WILHELM PEUKERT.

An important advantage of the electric light as compared with other systems of illumination, lies in the relatively far smaller amount of heat developed by the former for an equal intensity of light. Accurate calorimetric measurements of incandescent lamps have not yet been made public, and the results obtained with such lamps are therefore given below, whilst I reserve for a future occasion a report on corresponding experiments with arc lamps. The experiments may be of interest from another point of view, as they enable us to form a conclusion as to the economical utilization of the electric energy consumed by a lamp. The working of a lamp, other circumstances being equal, must be considered the more rational the greater the proportion of the electric energy absorbed which re-appears in the amount of light generated.

The experiments have been conducted in the electrotechnical laboratory of the Technical High School at Hanover, and it is my pleasant duty to put on record my obligation to Prof. Dr. W. Kohlrausch, who placed at my disposal the necessary apparatus, as well as to Herren Caspari and Ottesen, who took part in the measurements.

The determination of the heat evolved by the incandescent lamps was effected by means of a calorimeter. This consisted of a large beaker of thin glass, which was filled each time with a quantity of water carefully weighed.

The incandescent lamp in question was immersed in the water, which was continually kept well mixed by means of a simple agitator, and possessed a uniform temperature. This temperature was observed on a thermometer placed in the calorimeter, graduated in tenths of a degree centigrade. The calorimeter was fixed on a heat insulator, and to avoid as far as possible losses of heat to the surrounding air, a very slight difference between the respective temperatures of the air and the water was maintained during the experiments, amounting to 5° C. in one case only, and being in others always below this maximum value. That, in fact, the increase in the temperature of the water was little affected by the temperature of the air, is shown by the following rises of temperature taken at equal intervals of time, which in few cases differ by 0.1° C. The temperature of the work room increased only by 1° C. during the entire time of the investigation.

To ascertain the absorption of light, every lamp was determined photometrically, both when exposed freely and when placed in the calorimeter. As a standard of comparison, I used Von Hefner-Alteneck's normal flame. The current was furnished by a Schuckert's compound machine driven by a well-regulated Otto gas engine, so that the potential difference at the lamps, measured with a Siemens and Halske torsion-galvanometer, remained very constant. The strength of the current was determined with the same instrument by ascertaining the difference of potential at the ends of an accurately known resistance.

The results obtained are as follows:

SIEMENS AND HALSKE INCANDESCENT LAMP.

The lamp worked with a potential difference of 98 volts and a strength of current of 0·554 ampère, which values were found as the mean of all the observations executed simultaneously, which, as already mentioned, differed little from each other.

The calorimeter contained 2,471 grms. water, and if we calculate the value of the vessel in water as 79·1, the total quantity of water was 2,550·1 grms.

The observations were made at intervals of three minutes.

This rise of temperature of 0.7° in three minutes gives an hourly development of heat of 35.7 kilogram calories.

Thermometer.	Rise of Temperature.
14·9°	0·6°
15·5°	0·7°
16·2°	0·8°
17·0°	0·7°
17·7°	0·7°
18·4°	Mean 0·7°

The lamp when burning freely gave a light of 8·8 normal candles, and when in the calorimeter, 8·1.

EDISON'S INCANDESCENT LAMP.

Potential difference at the lamp = 93·6 volts; strength of current = 0·963 ampère.

Total quantity of water, 2,791·1 grms.

Observations at intervals of five minutes.

Thermometer.	Rise of Temperature.
14·65°	1·65°
16· 3°	1· 7°
18· 0°	1· 6°
19· 6°	1· 7°
21· 3°	1· 6°
22· 9°	Mean 1·65°

The rise of temperature of 1·65° in five minutes gives an hourly development of heat of 55·26 kilogram calories.

The lamp, burning free, gave a light of 16·9 normal candles, and in the calorimeter 14·4 normal candles.

SWAN'S INCANDESCENT LAMP.

Potential difference = 76 volts; current = 2·552 ampères. Quantity of water, 2,435·1 grms. Observations every two minutes.

Thermometer.	Rise of Temperature.
15·1°	1·7°
16·8°	1·7°
18·5°	1·7°
20·2°	1·7°
21·9°	1·7°
23·6°	Mean 1·7°

A rise of temperature of 1·7° in two minutes represents an hourly development of heat of 124·19 kilogram calories. The lamp, burning free, gave a light of 30 normal candles; in the calorimeter, of 28·2 normal candles.

BERNSTEIN'S INCANDESCENT LAMP.

Potential difference = 48 volts; current = 3·934 ampères. Total quantity of water, 2425·1 grms. The observations were made at intervals of two minutes.

Thermometer.	Rise of Temperature.
15·5°	1·1°
16·6°	1·1°
17·7°	1·1°
18·8°	1·1°
19·9°	1·1°
21·0°	Mean 1·1°

The rise of temperature of 1·1° in two minutes gives an hourly development of heat of 80·03 kilogram calories.

The lamp, burning free, gave a light of 52·1 normal candles, and in the calorimeter 51 normal candles.

Concerning this lamp, it must be remarked that the quantity of heat as determined is possibly too low, since losses of heat were not absolutely excluded in the experiment, owing to the construction of the lamp, which could not be entirely immersed in the water.

As the electric energy consumed by an incandescent lamp is converted into heat and light only, the portion of the total work of the current equivalent to the light evolved may be determined approximately, if not with absolute accuracy. An experiment may here be mentioned which was performed with an Edison A lamp.

It was placed in the calorimeter along with a vessel of thin sheet copper, so that light and heat were kept back. The amount of heat determined in this case agreed to two per cent. with that calculated from the potential difference and the strength of the current.

If we may assume that in the first-mentioned experiments the entire heat developed was absorbed by the calorimeter, and that the heat lost in the air was but small, which approximately speaking was the case, we obtain for the quantities of light evolved by the various lamps the following equivalent quantities of heat:

SIEMENS AND HALSKE'S LAMP.

	Kilog. calories.
Hourly quantity of heat corresponding to the work of the current	46·98
Heat equivalent to the light evolved	11·28
Hourly heat per normal candle	1·393

Consequently for this lamp, with reference to the absorption of light, the heat evolved hourly may be estimated at 37·73 kilogram calories, corresponding to 74 per cent. of the total work of the current, so that 26 per cent. of the current falls to the quantity of light evolved.

EDISON'S LAMP.

	Heat units.
Hourly amount of heat corresponding to the work of the current	78·01
Heat equivalent to light evolved	22·75
For normal candle hourly	1·58

Thus the heat evolved hourly by this lamp may be taken as 51·31 heat units. Hence 66 per cent. of the work of the current are expended in heat and 34 per cent. in light.

SWAN'S LAMP.

	Heat units.
Hourly amount of heat representing work of current	167·86
Heat equivalent to light evolved	43·67
Therefore for a normal candle hourly	1·549

The heat evolved by this lamp hourly is 121·4 heat units. Hence 72 per cent. are expended in heat and 28 per cent. in light.

BERNSTEIN'S LAMP.

	Heat units.
Hourly amount of heat representing work of current	163·43
Heat equivalent to light evolved	83·4
Therefore hourly per normal candle	1·635

The hourly heat for the lamp is therefore 78·24 heat units. Of the total work of the current, 48 per cent. is expended in heat and 52 in light. This high percentage may be due to the circumstance that, as already mentioned in the experiments with this lamp, considerable losses of heat were not excluded. Indeed, the percentages of the work of the current assigned here to the production of light can only be regarded as the superior limit. Experiments more precise than those here described may possibly yield lower values.

If the hourly quantities of heat per unit of light are calculated into their equivalents of mechanical work, we obtain the mechanical work per second equivalent to a unit of light (and therefore for a magnitude which may be regarded as the mechanical equivalent of this light), the following values: 0·16 kilogrammetres (Siemens and Halske), 0.18 (Edison), 0·18 (Swan), and 0·19 (Bernstein). These values show a sufficient agreement for the experiments just described, but can by no means be regarded as giving an accurate value for the mechanical equivalent of light. Indeed, the experiments were not conducted with any such intention. These results are merely mentioned here as a

Digitized by Google

corollary of the experimental conclusions, perhaps not quite devoid of interest.

For the sake of comparison, the amounts of heat obtained with other sources of light are tabulated along with those found with incandescent lamps. The hourly quantities of heat evolved are:

	Heat units.
Incandescent lamps. Siemens and Halske	427
" " Edison	355
" " Swan	430
" " Bernstein	153
Gas. Siemens' regenerative burner	1,500
" Argand	4,860
" Two-hole burner	12,150
Petroleum. Round burner	3,360
" Small flat burner	7,200
Solar oil. Schuster & Bauer's lamp	3,360
" " Small flat burner	7,200
Rape oil. Carcel lamp	4,200
" " Reading lamp	6,800
Parafiine candles	9,200
Spermaceti candles	7,960
Wax candles	7,960
Stearine candles	8,940
Tallow candles	9,700

The above mentioned experiments have led me to undertake a close investigation into the conversion of electric energy into light and heat, both in incandescent lamps and arc lamps. A memoir on this subject will shortly appear.

INCANDESCENT LAMP ECONOMY.

BY W. D. WEAVER,

(Assistant Engineer United States Navy.)

In an article[1] that appeared under the above caption in the columns of the April number of THE ELECTRICIAN AND ELECTRICAL ENGINEER, the writer gave a formula and its deduction showing the relation between the life of an incandescent lamp, its cost, the cost of the energy transformed and the resulting candle power.

The formula given was

$$y = \frac{b}{l\,x} + \frac{a\,k_1\,x^{\frac{1}{n}}}{746\,x} \qquad (1)$$

where y=total hourly cost of unit light.
a=total hourly cost of one electrical h.p. delivered at the lamp.
b=cost of lamp.
l=life of lamp.
k=constant of given lamp.
x=c. p. of lamp.

From the most reliable experiments then available, a numerical value of 2.7 was deduced for n. Subsequently, however, from more reliable and satisfactory experiments, a somewhat higher value for n has been deduced, and this value, 2.85, is probably very nearly correct.

In the same paper it was shown that if a relation could be established between the c. p. of a lamp and its resulting life, a value may be deduced for a c. p. at which the cost of the light will be a minimum, and the equation $l = k\,(m-x)^n$ was suggested as being likely to express this relation.

Since the appearance of the paper, there has been communicated to the writer the result of elaborate sets of experiments to obtain this relation. Calling l the life of a lamp at its normal c. p., C, and l' its life at any other c. p., C', it was found that the relation, $\frac{l'}{l} = \left(\frac{C}{C'}\right)^{3.65}$ holds true "for even the widest ranges of c. p."

As l and C are constants, the formula may be expressed, using the same notation as in formula (1) $l = \frac{k_2}{x^{3.65}}$ (2). By substituting l in (2) for l in (1) and differentiating, a value of x will be obtained at which the cost of the unit light will be a minimum; in order to make the solution more general, let $3.65 = m$ so that (2) will be $l = \frac{k_2}{x^m}$.

Substituting in (1)

$$y = \frac{b\,x^m}{k_2\,x} + \frac{a\,k_1\,x^{\frac{1}{n}}}{746\,x}$$

Reducing $y = \frac{b}{k_2}x^{m-1} + \frac{a\,k_1}{746}\,x^{\frac{1-n}{n}}$

Differentiating and placing $\frac{d\,y}{d\,x} = o$

$$\frac{d\,y}{d\,x} = \frac{(m-1)\,b}{k_2}x^{m-2} + \frac{(1-n)\,a\,k_1}{746\,n}x^{\frac{1-2n}{n}} = o.$$

Whence $x = \sqrt[\frac{m\,n-1}{n}]{\frac{a\,k_1\,k_2\,(n-1)}{746\,b\,n\,(m-1)}}$

Substituting for n and m their respective values, 2.85 and 3.65, and reducing, we have finally

$$x = .08734\ \sqrt[3.29]{\frac{a\,k_1\,k_2}{b}}$$

From the above equation, the following tables have been deduced. In the first table it is assumed that the life of a lamp at its normal (20) c. p. is 1,000 hours, and in the second table, 2,000 hours. The figures in the first column are the watts with which the unit light is produced at the normal c.p.; the cost of the hourly h.p. is given in the second column in cents, and is the entire cost of an electrical h.p. delivered at the lamp, interest on, and depreciation of plant being taken into consideration; the cost of a lamp is given in cents at the head, and the remaining figures are the respective candle powers at which the cost of the unit light under the conditions given is a minimum.

TABLE I.

Life at Normal C. P. (20)—1000.				
Efficiency of lamp.	Cost of hourly h.p.	Cost of Lamp.		
		50	75	100
2.5	4	21.9	19.8	17.7
	7	25.9	22.9	21
	10	28.9	25.6	23 4
3.5	4	24.3	21.5	19.6
	7	28.8	25.4	23.3
	10	32	28.3	27.2
4.5	4	26.2	23.2	21.2
	7	31	27.4	25.2
	10	34.6	30.5	28

TABLE II.

Life at Normal C. P. (20)—2000.				
Efficiency of lamp.	Cost of hourly h.p.	Cost of Lamp.		
		50	75	100
2.5	4	27	25.5	21.9
	7	32.1	28.8	25.9
	10	35.7	31.5	28.9
3.5	4	29.9	26.5	24.2
	7	35.5	31.4	28.8
	10	39.5	35	32
4.5	4	32.3	28.5	26.2
	7	38.3	33.9	31.1
	10	42.7	37.7	34.6

As the exponent, m=3.65, was determined for but one kind of lamp, it can only be provisionally accepted until experiments with other lamps have been made.

As the life of a lamp is also dependent upon the source of power, being much longer if fed from secondary batteries, it will be interesting to know if such variation will affect the exponent or only the constant.

Experiments in this direction will be of the greatest value, and if it is definitely proved that the life of a lamp varies according to an empirical law such as the one given, one of the most important problems in electric lighting will be solved. Thus, if the value of m given is nearly correct and general, it will be seen from the tables that in the majority of cases at the present time, lamps are used at too low candle powers.

BOGUS TELEGRAPH SCHOOLS AND THEIR METHODS.[1]

Among the many traps for the unwary to be found in New York none is bolder or meaner than the bogus school for telegraph operators. In the columns of the daily papers advertisements like the following can be seen every day:

Wanted.—7 young men to learn telegraphy; salaries guaranteed when qualified—$45 to $125 monthly.

Wanted.—5 young gentlemen and 4 ladies to learn telegraphy; good positions, when competent, at salaries from $45 to $125 monthly; every graduate obtains a steady situation as soon as qualified.

The victims are always young people who have but little money, and who are ambitious to improve their positions in life. They are usually working girls who have to work ten hours a day in dusty shops for a pittance, but who, in the hopes of gaining a livelihood in more cheerful surroundings, starve and pinch themselves until they obtain the money necessary to pay the tuition fee of a schoolmaster who professes to teach telegraphy, and then rob themselves of needed sleep and rest in order to attend the school. After months of anxious labor they receive printed sheets of paper that are called diplomas, but when application is made for the "positions when competent at salaries from $45 to $125 a month," they find that the snapper of the whip is in the words "when qualified," and that no amount of instruction in the school could make them qualified. In other words, they have been deliberately deceived by the advertisements and circulars of the school, and the money which they saved by going without food has been taken without any return.

The advertisements are fraudulent in wording. They specify that five or seven young people are wanted, because the thoughtless are thereby led to think that these numbers are called for to fill definite vacancies. If the person who reads the advertisement answers it by letter he will receive in return a circular that is filled with statements invariably false or misleading. Thus the circular from a Broadway concern says:

We are often asked what is the probability of obtaining a position at the end of the term. We answer positively that any person having a knowledge of the business will surely obtain a position. Hundreds of our operators are now filling responsible positions both in the east and west.

Mr. J. B. Taltavall, the editor of the *Telegraphers' Advocate*, read that part of the circular, and said:

"A friend and I called at that place one day and had a talk with the assistant. The manager couldn't talk, because he was blind-drunk. 'How great a per cent. of your pupils really become operators after they leave you?' I asked. 'No per cent.,' he said. 'We never got a job for one of them. But we fill the contract; we can get them work if they ever become qualified.'"

"Was that true?" was asked of Mr. Taltavall.

"No it wasn't. They couldn't get a job for any one, because managers won't look at a school operator."

At the office of superintendent Humstone of the Western Union Telegraph Company, a young man was asked if a graduate of a telegraph school could obtain a job, provided there was a vacancy.

"We do not discriminate against those who attend the schools," he said. "We treat all applicants alike. If graduates, as you call them, go somewhere and learn the business after they leave the colleges, they stand as good a chance as anybody."

"But do they learn the business at the colleges?"

"They do not. It is utterly impossible. They learn the alphabet and nothing more. Learning to operate a telegraph instrument is something more than learning the alphabet. You might as well expect a man to make a revised translation of the Scriptures after learning the Greek alphabet as to expect him to get a job in this office after going through one of these schools. At the same time we favor one school to a certain extent, the one in Cooper Union. Girls can learn the rudiments there, and we occasionally take those that are most intelligent and place them in the forwarding offices, or the little places at street corners and ferries, where a dozen or two messages are sent in a day. There they have plenty of time to work out a message, and some of them become valuable operators. It takes years of practice to make an operator, though."

"These schools, in their advertisements, say that graduates can obtain employment where the pay runs from $45 to $125 a month. Are salaries as good as that?"

"There is not an operator in the country that makes such wages. There are plenty of operators working for $30, and there are instances where a few first-class cable men get as high as $90. The advertisements are frauds."

Edward E. Todd, an experienced operator, went around to several of the schools in this city to learn the actual value of the instruction given. The schools were in little 7 by 9 rooms, with tables placed around under signs marked "Chicago," "St. Louis," "Boston," etc. Girls outnumbered the young men very largely in the rooms. The students pounded the instruments in a way that set his teeth on edge, but the work of the instructors was about as bad. One boy with an impudent face said he had learned the business in three months, and was then made an instructor. The operator, who was standing near a table, touched a key, making a meaningless sound.

"Ha!" said the boy, "do you know what you made? It was the word 'the.'"

"Make it again," said the operator.

The boy rattled off t-p-e, and then confidentially remarked that there was no business in the world that was so easy to learn, or so fascinating to those who had learned it, as telegraphing. One school advertised its long-wire service, which consisted of a wire running for two blocks over the houses. The instructor represented that practice over this wire would enable the students to acquire the proficiency necessary to operate Chicago or St. Louis lines. As a matter of fact, the wire was no better than if it had been ten feet long, and if it had been ten miles it would have been equally worthless for instruction in long-wire practice.

This operator found that the managers of the schools did not hesitate to forge names to their certificates of good character. One manager, with whom the operator was acquainted, had formerly been employed regularly in this vicinity, and when he opened his school got his acquaintances to sign letters of recommendation, which he afterward used as testimonials for the school. In some instances letters have been printed that were never written by the people whose names were signed. One manager had to be threatened with prosecution for forgery by an operator whose name had been used.

"Do the schools never graduate a pupil who eventually becomes an operator?" was asked of editor Taltavall.

"Now and then a student is particularly ambitious, and is naturally adapted to the business. If he has enough money he may learn the business. The manager, after graduating the youngster, offers the manager of some office a fee to give the pupil a chance to learn. Not long ago one of these schools had printed in the Western Union organ a standing offer of $10 to any manager who would allow the pupil to hang around his office and do such work as he could. Of course the work was to be done without compensation, and the pupil had to put up the $10. Some managers took it up; they kept the pupil around for a week or two, and then kicked him out to make room for another pupil with the $10 bonus. The treatment of these ambitious young people is shameful. Even where the graduate is apt he finds, when he has paid his bonus and has gone to work in a regular office, that he has first to unlearn all that he learned in the school. His time and

1. New York *Sun*.

Digitized by Google

money spent in the school were worse than wasted; but if he has the pluck he can still learn the business. A great many boys and girls come in from the country to learn the business. Schools are sometimes established in small provincial cities for the benefit of rural greenhorns. I have exposed a number in the *Advocate*, but only operators read the paper, and so the exposure does no real good. The instructors say the *Advocate* opposes the school because the Telegraphers' Brotherhood wishes to limit the number of operators. The fact is, the schools help to limit the number of operators by disgusting young men and women who would otherwise learn the business in some office where practical work was done.

"There is another feature of these schools which ought to be mentioned, and that is their moral influence on young girls. The schools are located on top floors and in back rooms, and designing men have every advantage. In fact the assistant manager on whom I called with a friend, as you have already written, boasted of his crimes against virtue."

The prices charged vary. One circular puts the price at, "per term of three months, $35—$15 upon entering and $10 per month thereafter until the full amount is paid, or $30 if all paid in advance. The instruction lasts twelve hours a day, ending at 9½ at night." Another circular, under the head of "extra inducement," says: "We will make the scholar a proficient operator for the sum of $25, in advance." This same circular says, under the head of "time in learning," that "four hours a day, from four to five months of close application, will be found sufficient time for all persons of ordinary ability."

Careful inquiry at the time of the strike of the telegraphers showed that there were plenty of operators waiting for vacancies, while the number now unemployed and waiting for an opening is probably much greater than the number actually employed. Even if the schools gave valuable instruction, and work could be obtained at once, telegraphing would not be a desirable business to learn; the pay of the skilled operators is not as high as that of many mechanics of corresponding ability, while clerks or expert bookkeepers make better wages. The work seems to be easy to those who have never done it, but it is, in fact, very hard, and wears out the operator rapidly, as many a man, gray before his time, is willing to testify. Another objection to the work is that there are but two telegraph companies, and these may be consolidated at any time. While men can only make $15 a week working for them, they are liable to lose even that if they displease the one boss who rules them. A discharged operator may get work on a railroad, but the pay runs from $7.50 to $10 a week in the country, wages which even the cloakmakers in the east-side tenements refuse to accept.

LAWS OF THE CHARGE AND DISCHARGE OF ACCUMULATORS.[1]

In a preceding article we described the methods followed by Messrs. Crova and Garbe for observing and registering the phenomena attending the charge and discharge of accumulators. These results, obtained by the method of registration, are most interesting, and form the subject of a communication presented, on behalf of the experimenters, to the Academy of Sciences recently by M. Faye.

It will be remembered that the accumulators used were those of M. Planté, perfected by M. Faure; each of them was formed of 12 plates of 1.1 d.m.q. (4.3 square inches) on each face, equivalent to an active surface of 26.4 d.m.q. (103.2 square inches) at each pole.

1st. *Phenomena of charge.* The quantity of the charging current being considerable (12 ampères), the weight of the plates diminishes rapidly, but a liberation of gas from their surfaces takes place at the end of three hours; this liberation does not indicate that the accumulator is saturated, for the inclined right line which defines the rule of charge[2] begins then to bend by turning its concavity towards the axis to which it tends to become parallel; it then becomes wavy on account of the liberation of gas which causes the balance to oscillate gently, and at the end of a sufficient time (about eight hours), it becomes straight and parallel to the axis, thus indicating the limit of charge; the total diminution in weight for the whole charge being 148 grammes (about .02 oz avoirdupois). In proportion as the charging current is feeble, the later does the liberation of gas appear; with a constant charge of three ampères, it is only manifested when the total charge is acquired.

The liberation of gas should be avoided as much as possible; in fact it shows a loss of energy not absorbed, and contributes to the disintegration of the active layer; when this occurs brown and gray flakes of bi-oxyd and of sulphate are seen to become detached from the plates and fall to the bottom of the cell.

The quantity of the charging current ought not then to exceed a certain limit, which is that under which the liberation of gas is only manifested when the plates are saturated; that is, when they cease to diminish in weight.

2d. *Phenomena of discharge.* The accumulator being closed on a known resistance, the law of uniform delivery begins almost instantaneously; the quantity hardly varies at the start and rapidly attains a remarkable constancy; the register then traces a straight line which is more inclined over the axis of the abscissæ in proportion as the delivery is greater.

At the end of a time varying with the quantity of current discharged the straight line bends rapidly; the delivery diminishes suddenly and the accumulator traces a line much less inclined, which ends by degenerating into a very long curve tending to become a straight line parallel to the axis of the abscissæ, the exhaustion is then nearly complete.

The second condition, that of feeble and variable discharge represents a fraction, practically wasted, of the charge. As the quantity of the current of discharge is greater, so is the straight line, which represents the practically useful and constant discharge, inclined and short; the longer also is the duration of the residual discharge corresponding to a feeble potential; after a powerful discharge of 8.4 ampères, having lasted only 3 hours, the condition of feeble discharge has lasted 115 hours and represented ⅝ of the total charge, only ⅜ of the total charge being utilized. In these cases it is necessary to re-charge the accumulators in order to saturate them anew, without trying to use the residual charge; but then it appears as though the capacity of the accumulator was reduced to a fraction as much more feeble as the quantity of the current of discharge is more considerable. The feebler the current of discharge the more the constant condition is prolonged; with a current of 3 ampères we have had a constant delivery during more than 15 hours; in this case the fraction of the charge utilized was ⅘ of the total charge; with a smaller delivery still, the useful return would be still greater.

During the intense discharge the chemical action is localized on the portions of the active layer immediately in contact with the lead; if the current of discharge is feeble, the chemical action tends to equalize itself through the thickness of the layer; the more rapid it is, the more does the layer of sulphate formed at the contact with the lead, tend to separate from the remainder of the active layer. Also, if, after having established a rate of discharge determined, the circuit be interrupted, we see the balance trace, no longer a straight line parallel to the axis of the time, which indicates the absence of change in the weight of the plates, but an ascending curve, which tends only slowly to become parallel with the axis; we see that under these

1. *Revue Industrielle.*

2. This line has for its axis the abscissæ of the axis of the time, and for axis of the ordinates of the variations of weight of the accumulator.

Digitized by Google

conditions, the accumulator continues to make sulphate for some time on open circuit, showing thus, reactions which are produced in the thickness of the active layer, without emission of current, between the lead, the sulphate formed, the remaining bi-oxyd and the free sulphuric acid.

3d. *Phenomena produced in open circuit.* This method allows of the prolonged study of accumulators even on open circuit. In the latter case the register traces a right line parallel to the axis of the time, indicating that the charge is preserved without loss.

Nevertheless, if, after having charged accumulators with a powerful current, with abundant and long continued liberation of gas, the circuit be left open, the balance shows a relatively feeble and very slow increase in weight (5 grammes), at the same time the voltmeter shows that the potential, starting at 1.92 volts, tends slowly to a constant value of 1.87 volts. This probably results from the influence of the gas retained in the active layer. At the end of a short time the accumulator finishes by acquiring a constant weight and potential, and this constancy is maintained during the whole time of registration (40 hours).

Conclusions. The potential corresponding to the rate of charge is constant, as long as the register traces a right line inclined; the liberation of gas is not an indication of saturation, it is a cause of loss of energy and of destruction of the layer, which appears as much earlier than the completion of the saturation in proportion as the charging current is more powerful.

Rapidity of delivery has for result the diminution of the capacity practically utilizable; the chemical work immediately following the interruption cannot produce any useful result subsequent to the uniform delivery; for the effect produced, energetic at the moment of closing the circuit, decreases rapidly and is exhausted almost immediately.

Thick layers of active matter are then useful only when the delivery in relation to the unit of surface is sufficiently feeble, about .1 ampères per square decimeter (3.9 inches) of active surface; it is therefore advantageous, in the case of a powerful delivery, to augment the surface of the plates and operate on layers relatively thin; the limits within which we can usefully increase the thickness, depending on the delivery per unit of surface of the plates, and probably also on the constitution of the active layer, varying with the mode of construction or of formation.

ABSTRACTS AND EXTRACTS.

STREET CAR MOTORS.

Every day the demand for an acceptable street car motor becomes more apparent. Against motors so far tried there have been more or less objections, but to the observer it hardly seems that any of them have been tried with very much persistency. Many objections to something so much of an innovation as the doing away with horses on street cars, are simply prejudices which a reasonable amount of persistence would overcome. If it were not for the fact that it is so easy to fall back upon the use of horses, no doubt a motor entirely acceptable would have been found before this, but it seems to be easier to go back to the old method than to persevere in overcoming the difficulties that may be expected in the way of the application of any motor. There is a place for a motor that is just right, but the owners or officers of street roads have so far shown but little patience in their trial; they expect impossibilities in the way of something that shall be just right at the first trial. An electric motor for street roads would seem to possess special advantages, but does not seem to receive much attention. The first successful motor for this purpose that is placed on the track will have an important start in the race. In the meantime, unless there is more activity in the matter, wire cable propulsion may be improved until the introduction of any motor will be more difficult than at present. Important improvements are believed to have been recently made in cable roads, and perhaps with others to be expected it may be found the most desirable means of operating surface roads. However this may be, it is reasonable to suppose that horses will not always be used for the purpose.—*American Machinist.*

A NEW INCANDESCENT LAMP.

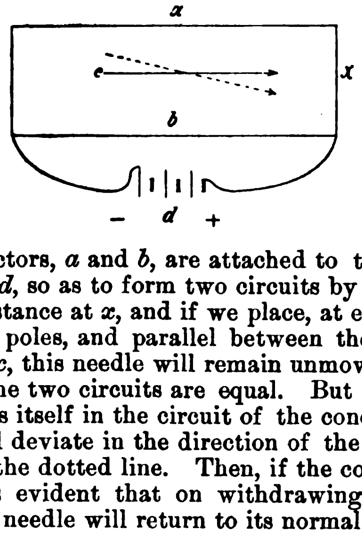
Mr. Max Muthel has patented in Germany an incandescent lamp which possesses the advantage of requiring no vacuum in the globe. He has very ingeniously overcome one danger that experiments of this kind have hitherto presented, and that is the fusion of the incandescent wire. The wire used by him consists of a mixture of bodies that are conductors and non-conductors of electricity.

He takes magnesia, silicate of magnesia, etc., and porcelain clay, and forms a fine thread of them which he heats to incandescence and saturates with a solution of platino-iridium salts, and afterward raises several times to incandescence in order to reduce the absorbed salts to a metallic state. Instead of the foregoing mixture, filaments of clay may be taken and saturated with a solution of a metallic salt, which is then reduced to a metallic state through incandescence and the use of oil of lavender or some other organic substance, or through an electric current. With wires thus prepared fusion is absolutely overcome, the presence of the non-conducting substances preventing the metallic parts from melting. Mr. Muthel supposes that the electric spark jumps, so to speak, from one particle to another, and in this way causes a heating of the other substances, which, brought to incandescence, emit a more intense light.

In order to make the filaments stronger they may be covered with chrome, the melting point of which is still higher than that of platinum. To effect this the filament is placed as an anode in a bath of chloride of chromium. —*La Lumiere Electrique.*

MICRO-OHM MEASURE.

In the various kinds of apparatus hitherto employed to measure electric resistances, irregularities in the indications frequently and almost inevitably occur. The chief causes of irregularity arise from the use of a plug commutator, which allows of sensible differences in the indications of resistance, because of the more or less perfect contact produced on inserting the plugs. M. Maiche has invented an apparatus whose performance cannot give rise to any error of indication. The principle can be thus explained:—



If two conductors, a and b, are attached to the two poles of a battery, d, so as to form two circuits by the interposition of a resistance at x, and if we place, at equal distance from the two poles, and parallel between them, a magnetized needle, c, this needle will remain unmoved if the resistances of the two circuits are equal. But if the resistance, x, exerts itself in the circuit of the conductor, a, the needle, c, will deviate in the direction of the conductor, b, as shown by the dotted line. Then, if the conductor, b, is movable, it is evident that on withdrawing it from the needle, c, the needle will return to its normal position, and the displacement of the movable conductor will correspond exactly to the resistance measured. In the apparatus the needle is placed between two movable bobbins.—*Illustrated Science Monthly.*

EARLY HISTORY OF ZINC.

From the records of the Chinese we learn that they were acquainted with metallic zinc at a very early period. The metal was imported from India by the Portuguese in the seventeenth century, under the name of "spainter" or "spialter," before its nature was recognized in Europe. Whether the ancient civilized nations of the west were acquainted with metallic zinc cannot be ascertained; but there is a great probability that they were. The high degree of development of some of the ancient nations on the shores of the Mediterranean with regard to metallurgical operations, their very extensive manufacture and use of brass, make it most likely that they knew also metallic zinc and some way of extracting it from its ores. It is true that the writings of the old Greek and Roman authors do not refer to it; they regarded brass and yellow metal as only a colored copper, and the Greek word "chalkos," as well as the Latin word "aer," meant both copper and brass, though some authors, as Strabo and others, used sometimes the word "aurichalcum" for the latter. This, however, only related to the color, and meant nothing but a gold-like copper. If we consider the difficulty of communication and the continued and violent political revolutions in the ancient world, the absence of all the present facilities for spreading and preserving any knowledge, and, further, the fact that our historical sources consist chiefly of the fragmentary writings of a few philosophical scholars, we may easily conceive the possibility that some ancient knowledge may have been entirely lost to us. Our oldest historical documents—the writings of Aristotle and Dioskorides—refer to the manufacture of brass, by admixing an earthy substance, "kadmea," with the copper. The latter also mentions the application of zinciferous deposits from the brass kilns for the same purpose, and distinguishes from it the white oxide or flowers of zinc, under the special name of "pompholix." In his description of the latter substance he compared its appearance to that of wool, which gave rise to the new alchymical name of "lana Philosophica," much used by the authors of the middle ages.—*Industrial World.*

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed Editor of The Electrician and Electrical Engineer, 115 *Nassau Street, New York city.*

FACILITIES FOR INVENTORS.

[39.]—I observe that the London School of Electrical Engineering makes the following offer to inventors: "Inventors provided with every facility and the use of all necessary plant and machinery for testing or working out electrical inventions and improvements of every description. The utmost secrecy guaranteed, and advice given as to commercial value of new inventions. Private rooms and high professional assistance if required."

Is there any reputable school in this country which offers such facilities? I am aware that there are places where one can get work done at high prices, as in any shop, exposed to the gaze of crowds of students and visitors; but I do not know of any such facilities as those above offered. There certainly should be, however, in this home of inventors, with its boasted superiority to other lands. C. E. F.

CORRESPONDENCE.

NEW YORK AND VICINITY.

The Sale of the Bankers and Merchants' Property.—A Busy Day for Railroad and Telegraph.—The $5,000 Gift of the Western Union Telegraph Co.—Burglary Running to Seed.—Electric Time.—A New Telephone Proclamation.—Storage Batteries on the P. R. R. —The Commercial Telegram Co. Still Lively.—Ventilation of the W. U. Operating Room.—The Underground Commission.

The financial difficulties of the Bankers and Merchants' system appear to have been at least temporarily tided over, by the sale of the property to Edward S. Stokes, representing the newly organized United Lines Telegraph Co. The first steps to be taken are the liquidation of the claims against the property, which will require an expenditure of about a million and a half. Under the existing condition of telegraph affairs, it appears probable that considerable more money must be sunk before the system can be placed on a paying basis.

The Grant obsequies, Aug. 8, taxed the resources of the railway and telegraph companies in the city to an unusual extent. About 800 regular trains passed in and out of the Grand Central depot, many of them in two sections, in addition to which there were about 400 special trains. These trains were handled as rapidly as they arrived, and in perfect safety, as the interlocking switch and signal system worked admirably. About 93,000 messages were handled in the Western Union main office, and the telephone people were kept exceedingly busy. It is doubtful if any city in the country could have furnished equal facilities for moving and providing for such an immense gathering of visitors.

The appropriation of $5,000 by the Western Union Telegraph Co. for the Grant monument fund created considerable surprise among those who have been familiar with the latter-day policy of the great corporation. It certainly appears that a more liberal treatment of the living would be in better taste. It is to be hoped that this gift will not be followed by another "sliding scale" reduction, as was the case only a few years ago immediately after a large donation to the Vanderbilt university by one of the heaviest stockholders in the company. The following intimation that its officers and employés are expected to follow the example, should be especially relished by those who are called upon to perform extra service without compensation:

Western Union Telegraph Company,
Executive Offices, Aug. 12, 1885.

Resolved, That the general manager be requested to designate some officer of the company whose duty it shall be to receive from the officers and employés of the Western Union Telegraph Co. such contributions as they desire to make to aid in the erection of a national monument over the remains of General Grant, and that all sums so contributed shall be paid to the Grant Monument Association as the contributions of the officers and employés of the Western Union Telegraph Co. A. R. Brewer, Secretary.

Some time ago attention was called to the fact that burglary was waning as a profession, by reason of the protection afforded to property by the various electrical devices now so generally used. That the cracksmen are in a desperate condition is apparently confirmed by the fact that they broke open the cash drawer of the telegraph office at Castle Garden a few nights ago, and secured something over a dollar, mostly in pennies.

The local business of the Time Telegraph Co. has been transferred to the New York Electric Time Co., which has acquired the franchise and plant for the cities of New York and Brooklyn, also Long Island and Staten Island. This service has been very popular and satisfactory, and deserves to be still more extensively used. The office of the local company is at 15 Cortlandt street. The parent company will confine its business to the production of apparatus and the organization of sub companies.

An anonymous proclamation has recently appeared as an advertisement in one of our dailies, supposed to have been issued by the National Improved Telephone Co. It says that in addition to Philipp Reis; Holcomb, Gray, Edison, Van der Weyde, Pickering and Cross, all made speaking telephones long before Bell was known as an inventor, while the telephone made by Bell in 1876 was a failure. After devoting half a column of fine type to the misdeeds of the Bell company, it winds up with the following query: "How long will this patient people submit to these outrages?" We suggest that this terrible state of affairs is likely to continue at least eight long and weary years, but that meanwhile existence may be rendered comparatively happy by dispensing with the use of the telephone. It is different with a hand organ, to which one is often forced to listen, even when he does not subscribe for its support.

The Pennsylvania Railroad Co. is systematically continuing its experiments with storage batteries and incandescent lamps for the lighting of its parlor cars running between Jersey City, Philadelphia and Baltimore. The cells are charged at Jersey City, and supply the lamps for about seven hours. The arrangement appears to be superior to that of carrying gas in a reservoir, but no statement of the comparative expense has as yet appeared.

Digitized by Google

The Commercial Telegram Co. continues to furnish quotations as of old, and is making an addition of two large dynamos to its already very complete plant. The same system is being started in Chicago and Boston, and will doubtless appear in other large cities very soon.

There is an immense field in New York for the introduction of small motors, driven by the agency of electricity. One of the favorite arguments in favor of the electric light as an investment was, that the power could be utilized during the day for such service. A Sprague motor is doing excellent service at the Western Union building, where it drives a ventilating fan on the south side of the operating room, which has been found to give great relief to the inmates, who have long suffered from the vitiated atmosphere prevailing there.

The commission on electrical sub-ways has held several meetings for the reception of plans for burying the wires. The following resolution was adopted August 18th :

Resolved, That every corporation, association or person using or desiring to use any electrical conductor in the city of New York, do forthwith file with this board such map or maps and other suitable descriptions as will fully inform this board concerning the location, courses, termini, space and all other details and requirements concerning the electrical conductors operated or desired to be operated by such corporation, association or person in the city of New York, to the end that this board may be enabled to make due provision for said conductors in the general plan and subway to be devised as aforesaid, and which it has full authority to require to be used for all the electrical conductors aforesaid.

The action contemplated by this resolution will necessitate intelligent study, to ascertain where the conduits should be provided and how many wires are to be accommodated. As the bereaved husband remarked to the sexton who was digging the grave, "let it be deep,"—when the wires are down, we want them to remain.

NEW YORK, August 24, 1885.

CHICAGO.

Frequent Storms, Cyclones, and Curious Freaks of Lightning—Rival Panoramas with Rival Arc Lamps.—Opening of the Grand Opera House.—Arc Lamps Ordered Off the Freeport Court House.—Return of the Western Union Pilgrims from California.—The City Hall Provided with Edison Lamps, Telephones and Lightning Rods.—The Field "Ticker" System Makes its Appearance.—Changes in the Board of the Western Edison Co.—An Arc Lamp Plant Raises an Alarm of Fire.

THE poet who sang:

"I would not live alway, I ask not to stay
Where storm after storm rises dark o'er the way,"

would hardly have selected Chicago, or for that matter, any part of the west this season. During some three or four weeks the elements have served us up a storm for breakfast nearly every day, and sometimes two or more at a meal. In nearly every instance these have been peculiar, and often quite novel in their manifestations. People have been struck without any more serious damage than having a boot sole torn off, an iron tool ruthlessly jerked away from them, or some other odd result, accompanied by a severe but not lasting shock. In one or two instances telegraph line repairers have been suddenly tumbled off the pole by surcharged wires. Cyclones have waltzed over the country from beyond western Minnesota to the Atlantic, doing damage to crops, buildings and fences, scattering household utensils and furniture, and in not a few cases killing animals and people in their race. Shade trees of many inches in diameter have been uprooted, carried away, and finally dropped when the grim destroyer considered them no longer a novelty as toys.

A third panorama has just been inaugurated here, and was thrown open to the public on the first of August. The three are illuminated by arc lamps, and each by a different system. The "Battle of Gettysburg" is shown by Van Depoele's, the "Siege of Paris" uses the Jenney," and at the last, the "Battle of Shiloh," the Excelsior people have placed their lights, so that comparative estimates of the efficiency of the three systems for similarly illuminated pictures may be made by any one who desires, and he may view three grand battles, at 50 cents each, any day.

The Chicago Opera House opens under the radiance of Edison lamps, on the 18th inst. It is a beautiful theatre, with a seating capacity of about 2,000. Being absolutely fire-proof, with a multitude of exits, there would seem to be no reason why the enterprise should be other than a successful one, if proper attractions are offered. The internal arrangements are everything that could be asked—unique, original and beautiful.

The electric light people and the county commissioners at Freeport, Ill., are at loggerheads about the lights on the court house dome. The company refused to remove them in accordance with an order from the board, and the board, at last accounts, were debating what action they should take to compel obedience to the order.

Col. Clowry, M. C. Bristol and C. H. Summers, of the Western Union company, have just returned from the Pacific coast, where they have been on a tour of inspection. The party were somewhat delayed, as they tell the story, one of the three having borrowed the entire funds of the other two, and expended the sum—15 cents—in investigating the mysteries and Joss houses of Chinatown, it is said with the intention of writing a book of experience and warning to the telegraph fraternity.

Our city hall has been "all broke up" by the Edison people, who have had a pretty tough time of it wiring the building for their system of lighting. Perseverance has secured success, however, and the result is remarkably satisfactory. Immediately after that work was commenced, the building was wired for telephone connections running to all the heads of departments, making a little telephone exchange system by which each may call up and talk with any other of the departments without the intervention of any one; and the lightning-rod man got in his work in the meantime, his line running from the top of a 75 foot flagstaff surmounting the building.

The county building, which adjoins the city hall on the east, is being wired by the United States people, who will have an equally if not more difficult piece of wiring to do there.

An opposition to or competitor of the Gold and Stock company, is about to make its appearance. The name of the new company is the "Chicago Commercial and Financial News Co." They purpose using a new form of ticker, which it is claimed is superior to the old, and requiring but a single wire. The company have one duplex wire to the New York exchange, and claim that their list of subscribers is rapidly filling up. They have the assurance from the market quotations committee of the Board of Trade that they shall have equal facilities with similar organizations here. The affairs of the company are in the hands of Mr. Bruce and county commissioner Van Pelt.

Several changes have recently taken place in the Western Edison Light Co. here. Gen. Stager's death left a vacancy in the presidency of the company, and another in the board of directors. The former is now filled by John M. Clark, Esq., late vice-president, and his place by A. F. Seeberger, Esq. The Hon. Robert Lincoln, late secretary of war, has been placed in the board, vice Gen. Stager, deceased. And again, Geo. H. Bliss, Esq., the general superintendent of the company, has resigned, to retire the first of September. Mr. Bliss has labored long and faithfully in his position, and though repeatedly importuned to accept tempting offers outside the company, has as persistently refused to abandon his chosen occupation, and he does so now with the kindliest feelings, which are fully reciprocated by his late associates. He accepts the position of secretary and general manager of the National Electric Service Co. of the United States, a general organization for the manufacture, sale and installation of Johnson's electro pneumatic apparatus for the controlling of temperature in steam and water-heated buildings. A large field is open to the new enterprise, and there is every prospect of success foreshadowed by the new management.

At the southern limit of the city, on Cottage Grove avenue, a new arc plant was recently installed, and the light suddenly flashed upon the vision of a fireman in the adjoining town of Lake. As the source of light was hidden from view, and as he was unaware of the existence of the plant, duty compelled him to turn in a fire alarm. This is about as near as Chicago has ever come to having a fire from electric lighting, and should be noticed by the gas people as "almost a dangerous fire from electricity."

CHICAGO, August 21, 1885.

PHILADELPHIA.

Another Electric Railway Project.—The Baltimore and Ohio Company Secures an Entrance to Harrisburg.—The Gas Interests at the Novelties Exhibition.—Serious Disturbances Caused by Atmospheric Electricity.—The Government Seeks to Economize in Electric Lighting.—Final Explosion of the American Sectional Underground Conduit.—Space Still to be Had at the Novelties Exhibition.

AUTHORITY has been extended by the Ridge Avenue Passenger Railway Co. to the American Electrical Railway Co. to lay a conduit and experimental line on Ridge avenue, from the Dauphin street depot to Laurel Hill cemetery. This section of the road has been chosen for the experiment because of the heavy grades, and in order to show how the new motor can surmount them in all weather. The work of building the plant will begin shortly. The conduit will be laid so as to avoid interference with the travel of horses, and the tracks will not be disturbed. The conduit will be of heavy timber below the surface. Running along just below the top will be the compound conductor, of copper and iron, half circular in shape, well insulated, and protected from damage from outside influences. On the top of the conduit forming each side of the slot, which will have a half inch opening, will be iron plates about five inches in breadth altogether. This slot opening will not be directly in the centre of

Digitized by Google

the track, but to one side of the meridian line. The current will be transmitted by an ingenious contrivance from the conductor underground to the motor in the car, and will be under instant control of the driver or engineer. At intervals of 18 feet, plates will be arranged over the conduit which may be readily removed for repairs and other work, and without removing the body of the conductor. The bottom of the conduit will be cemented previous to filling in the ground about it. It is claimed that a speed of from 7 to 10 miles an hour can be attained for the experimental Ridge avenue line, with a saving of $2.50 to $3 per car over horse power.

At Harrisburg, on August 5th, the Baltimore and Ohio Telegraph Co. had the last barrier to its entering that city on the poles of the electric light companies removed by the court, which dissolved the injunction obtained against it last week by Charles H. Bergner. Argument was heard in the matter before Judge Sadler, who decided, in view of the fact that the defendant company did not now intend to string a cable near the premises of the complainant, that he had no standing. The new company will now commence business in that city. There was considerable interest in the matter, on account of the prevailing opinion that Mr. Bergner's action was in the interest of the Western Union Telegraph Co.

At the coming Novelties Exhibition the "gas men" are going to try very hard to oust the "electric light" people in public favor, as the managers of the Franklin Institute announce that it is gratifying to them to be able now to offer gas an opportunity of displaying its merits side by side with electricity. They assure the gas fraternity that the electricians will leave no stone unturned to demonstrate the cheapness and efficiency of their respective systems, and no half-hearted efforts of the gas men will offset the energy and alacrity of their rivals.

Electric storms have been quite frequent hereabouts of late. The nearness of the atmospheric disturbance to the earth was the marked feature of one of them. The thunder seemed to roll along the roofs of high buildings, and the lightning flashes to traverse the walls of top story rooms. The effect of the storm upon all electrical contrivances was apparent almost instantly. The lights at the ferries along the Delaware river were extinguished. There was trouble, also, in Washington, Franklin, and Rittenhouse squares. The work of transmitting and receiving the rush of telegraph matter was considerably impeded in the Western Union main office. Telephonic communication was for a long time suspended. At Lancaster, Pa., a telegraph pole was shattered and the lightning glanced off into the Pennsylvania railroad tower, igniting it; many wires were fused, and one of the operators was thrown to the floor and badly shocked.

Colonel Youmans, of the Treasury Department at Washington, was in the city a few days ago for the purpose of examining the system of lighting the post-office, with a view of reducing the expense thereof. He thinks that $500 a month can be saved in replacing 100 arc with large incandescent lamps. The cost of lighting the building at present is $2,000 per month.

The plant of the American Sectional Underground Conduit Co., which was laid along several blocks of Chestnut street, has come to grief at last. If you recollect, in a former number of the ELECTRICIAN AND ELECTRICAL ENGINEER I spoke of the explosion of foul air and gas in the man-holes of these conduits. They have become such a nuisance to people in general that workmen are now engaged in digging up the sections and carting them away. This is probably the best disposition to make of them.

The statement that has gained publicity, that no more requests for space will be granted at the Novelties Exhibition, is pronounced erroneous by the gentlemen in charge, as they have still considerable room left for desirable exhibits.

PHILADELPHIA, August 19, 1885.

BOSTON.

Electricity Given a Front Seat at the New Post-office.—Temporary Facilities of the Postal Telegraph Company.—The Judkins Electric Train Signals.—The Baltimore and Ohio reach Portland.—Present Officers of the New England Telephone and Telegraph Co.—Supposed Accidental Death of F. A. Gower.—A Jay Gould Story from "out west."

AFTER many years of toil and labor, the large and massive granite building used as the Post-office, Sub-treasury and United States Courts has been completed, and as a sign of its approach to completion the ugly fence which so long hid the front of the edifice has been removed, and the facade stands out in all the excellence (?) of government architecture. Its particular style one could hardly tell; the original designs were by the now celebrated Mullett, these were partly embodied in stone; then later genius took it in hand and completed it. For it has been one of the *glories* of this glorious country that no man, employed by the government ever lived, officially, to see the end of his labors from their beginning—"some other fellow" always comes in and makes "pi" of what has gone before, otherwise no one would know that he had ideas of his own. So the facade of the post-office, so called, fronting on Post-office square had to be re-arranged, and when all was supposed to be completed, two immense pieces of statuary were hoisted to the top of the walls. The building is of granite, and when these white marble pieces were in place they fairly stood out from their surroundings. They are, however, worthy of attention as being the work of one of our most talented young artists, M. D. C. French, of Concord, Mass. They are made of Vermont marble, and are 17 feet high. The group on the right, as it faces the square, represents Labor protecting the family and sustaining the Fine Arts; while the one on the left represents the purely modern idea of "Science controlling the forces of electricity and steam." This has three figures—Science in the form of a woman, seated in the middle, directing Electricity (a youth with winged feet) as she rests with her left hand upon the shoulder of Steam, who is chained to a wheel. The ideas sought to be conveyed by this statuary are: That Labor will protect the family and sustain the fine arts, and majestic Science will not be conquered, she will even direct the fiery element of electricity. The place given by the artist to electricity is significant. The strides that *that* child has made within a decade eclipse all other children of mother Science. Steam is great, even its capacities are not yet limited, but compared with electricity, the winged-footed child, it is indeed bound. Mr. French has been very successful in his art, and for one so young has achieved much.

The Postal Telegraph Co., which began business between Boston and New York a month ago, with an office at No. 4 Arch street, is still operating in an experimental way, transmitting its customers' despatches over the Commercial Cable Co.'s wires. It depends upon how the Bankers and Merchants' company's proceedings terminate to determine the future and permanent course the Postal company will take. At present its Boston office, quietly established, is but temporary, though the business is fair for the facilities in use.

The Judkins Electric Signal people are pushing their railroad train signal into use on the New England railroads. It gives satisfaction all around. One important feature of their devices, is the neat manner in which everything is worked out, all of their apparatus being effective and handsome in appearance.

The Baltimore and Ohio Telegraph Co. has extended its wires to Portland, Maine, and has reduced the 10 word rate to 10 cents. The Western Union company's charge has been 25 cents.

The Western Union Telegraph office in the Post-office building is one of the places in this city set apart by the national monument committee to receive subscriptions for the Grant monument.

The following is the roster of the New England Telephone and Telegraph Co. Theo. N. Vail, president; O. B. Parker, assistant to the president; Wm. R. Driver, treasurer; F. J. Boynton, secretary and acting auditor; J. N. Keller, general manager; W. J. Denver, assistant general manager (Mr. Denver has been recently appointed to this position, he has been manager of the Western Union Telegraph office in Springfield, Mass., for many years); John T. Wheeler, general superintendent; Chas. B. Wells, cashier; I. H. Farnham (formerly in charge of the telephone interests at Portland, Me.), electrician. David B. Parker is superintendent of the Boston division, having for his assistant in charge of the operating department, John J. Carty—who by the way is quite an inventor of telephone apparatus; the operating room contains many touches of his genius.

F. A. Gower who is supposed to have lost his life in balloon experiments, recently, in France, was connected with the early telephonic interests in this country and in this vicinity, several patents having been issued to him for telephone inventions. He with others inaugurated the telephone business in Paris, the Gower-Bell instruments being introduced there. He was said to have become quite wealthy.

An alarming letter appeared in the financial columns of the Boston *Herald* recently—purporting to come from the "rowdy west." The writer said it was rumored that the terrible Jay Gould, who appears to have nothing else to do, had secured a controlling interest in the American Bell Telephone Co., and had bloodthirsty designs upon all the local telephone companies; that as the inauguration of a gory and upheaving future, he had been the author of Mr. Vail's resignation from the general managership, and had speedily followed *that* up, by turning out Mr. Madden from *his* position. This financial-high-toppling letter writer says that western telephone stocks have been shaken by these reports, which would appear to have affected them something as a terrible cyclone would; and no doubt that when the western telephone stockholder hears the dreadful name of *Gould*, spoken in telephonic accents, he retreats hastily to his subterranean cyclonic chamber, and pulls the entrance hole in after himself. To one who knows that the Forbes, Hubbard-Bell and other connected and allied families hold the balance of the stock, and control the "monopoly," such hot weather yarns are extremely tiresome, and are in danger of giving one nervous prostration from their being so very wearisome.

BOSTON, August 19th, 1885.

ELECTRICAL NEWS AND NOTES.

NATIONAL ELECTRIC LIGHT ASSOCIATION.

SEMI-ANNUAL MEETING.

UNION SQUARE was enlivened on Monday evening, August 17th, with the presence of the advance guard of electric light representatives. The full attendance was in itself proof of the popularity of the Empire City for gatherings of this character. New York is perhaps less hospitable than some smaller towns, but visitors undoubtedly feel that they are at least granted the freedom of the city during their stay, and this in itself insures a pleasant trip.

The executive committee found ample business to engage their attention up to 3 P. M. on Tuesday, when the convention was called to order by President Morrison, who in his opening address remarked that among the subjects to be presented for discussion would be that of the proper insulation of lines; the feasibility and cost of underground wires for electric purposes; the comparative desirability of the tower system of lighting with that of lighting by poles; the comparative cost of producing electric lights by steam and water-power; electric motors and their relation to electric lighting in the production of power; the best form of dynamo; and the advantages of electricity over other illuminants for street lighting. An effort will be made during this convention to establish business relations between the different working companies; that is to say, to have such relations established as will lead to the establishment of a uniform price for electric lighting in the different parts of the country, and that without regard to the system by which the electric lights may have been produced. We propose to make an effort to bring about an equalization of the prices between the different manufacturers, so that, instead of destroying each other, this association may be the means of building up friendly relations between the different electric light companies of this country, and perhaps compel fairer play than you can coax out of what are known as the parent companies. That applies all the way down from the manufacturers of machinery to the manufacturers of carbon.

Mr. G. S. Bowen, chairman of the executive committee, reported that 62 names had been placed on the roll, and that $620 had been received by the treasurer, out of which expenses had been met to the amount of $415.67. The report was accepted.

An amendment to the constitution was also adopted providing for the admission to associate membership of "electricians, electrical engineers, and all those who are engaged in business collateral with electric lighting business," and to permit of the offices of secretary and treasurer being held by different persons.

The resignation of J. Summerfield Baldwin as secretary and treasurer was accepted, and the vacancy filled by the election of A. G. Rheinard, of Baltimore, secretary, and Charles Cooper, of Brooklyn, treasurer.

During the ballot for treasurer, which first resulted in a tie between Messrs. Linnell, of Hartford, and Cooper, Mr. Porter, representing the Pittsburg Carbon company, claimed the right to vote as an active member, on the ground that his principals operated an isolated plant, which at the first convention had been ruled as a sufficient qualification. Further inquiry developed the fact that the plant consisted of a one-light dynamo and a single Brush lamp. Notwithstanding the admission by the president that a Brush lamp was equal to 10 of any other pattern, he was constrained to decide in the interests of the association, and the Pittsburg gentleman was debarred from the right of franchise.

Quite a breeze was raised by the circumstance, however, which led to the presentation of an amendment to the constitution to the effect that the operating of electric light plants be construed as meaning only those who are carrying on a lighting business —not merely operating a plant for their own private purposes.

Mr. Wadsworth opposed the amendment, as follows:

"I hope this motion will not prevail, because, if it does, it will shut out from this convention the representatives of every mill in New England, and there are mills there operating plants of from 100 to 600 lights; and men operating a plant of that size certainly have a right to active membership here. It is desirable for the convention to get them here. It is desirable for this convention to hear from them the experience they have met with in operating those plants in cotton and woolen mills; and I know personally a good many of the representatives of those mills who are not only thoroughly posted in electrical matters, but who can give this convention, or any member of it, valuable information in regard to operating electric light plants. They operate all the various systems of the United States, both arc and incandescent, and at our meeting in Chicago we held out inducements to them to come here. We formulated this constitution with the understanding that they were to be represented, and I think at this late day it would be entirely wrong to say they cannot come into it."

Mr. Leggett—"I agree with Mr. Wadsworth's views with respect to the desirability of having such individuals or firms represented in this association, but it does not appear to me that they need to come here as regular members; but that the constitution, if it is not already by amendment made broad enough to permit these parties to come in as associate members, might be so changed as to permit them to come in as associate members without a vote. We can then have the advantage of their presence, and they can have the advantage of the association."

Mr. Duncan—"I think the amendment should prevail, for the very reason stated by Mr. Wadsworth in opposition to it. These mill men, when they see this association is run from a business standpoint, will then have some confidence in the association, and will be glad to become associate members and give us the experience of their training and their personal observation of their plant, but when they see that all outside interests, manufacturers of wire and everything else, may become full voting members in the association, they will lose confidence in it."

The chairman called Mr. Weeks to the chair, and said: "When the question of forming this association was first mooted at Chicago, this was one of the stumbling blocks in the way. It was discussed fully in all its bearings. The objection made there to the admission of such gentlemen as Mr. Wadsworth, such gentlemen as Mr. Porter, and other men who are virtually dealers in supplies, and not electric light men, was just such as Mr. Duncan has gone over now. On the other hand, the business in which they are engaged is so closely allied to that of electric lighting, being a part of the electric lighting business itself, you may say, it was very difficult to draw the line. The line was drawn, however, at this point—that a man who was a user of an electric light plant was entitled thereby to active membership in the association; but it was understood that the electric light plant so used was to be of sufficient size to entitle him to some consideration among electric lighting men. In other words, that the questions that would arise in this convention—that the result of questions, and the discussion upon them, would be for the benefit of the men who operate electric light plants. Now, I want to ask you, if a gentleman running a one-light Brush machine with one lamp in a carbon factory, representing the carbon interests absolutely and entirely, if he has sufficient interest in that one lamp burning out at Pittsburg to entitle him to be benefited in any way, so far as his electric light is concerned, by the discussions which take place in this convention? It was not the intention of the framers of this constitution; it was not the intention of the convention which adopted it; it was not the intention of the gentlemen who voted upon that constitution to make this association an association to advance the interests of men who dealt in electric light supplies. It was the intention of the framers of this constitution; it was the intention of the gentlemen who voted for the adoption of this constitution, that its beneficial results should accrue to those who were engaged in the business of electric lighting. But you will ask, 'Why do you take the money belonging to these gentlemen—Mr. Porter's company and others?' With a full knowledge on the part of Mr. Porter when he came into this room that he was only to be an associate member, he paid his $10 and received his ticket. In the hurry and bustle and crude form in which this association finds itself, starting on its first step before the public, Mr. Porter sits in the convention, and when his vote is required by some one else it is only then that he finds he is qualified to vote by reason of using a one-lamp Brush plant. Now, I assume that it is not the intention of this convention to depart from the principle it has adopted to make it an electric lighting association. The information which the members of the Electric Light Association receive from the dealers in electric supplies makes it very desirable that these gentlemen should be associate members of this association. The benefits which the dealers in supplies receive by being brought face to face and directly in contact with the men who consume their articles, make it desirable for them to be associate members, and thereby recoup themselves for whatever expense they may have incurred to attend this convention. I therefore assume that it is desirable on both sides to have the gentlemen in this business in this association. I feel it desirable, but it was believed proper and right to draw the line somewhere, and the line was drawn, as I have endeavored to explain to you. I have no objection to Mr. Porter; I have no objection to the representative of Benedict & Burnham, who operates a plant of 36 lights, and who asks me, 'Am I not eligible to active membership?' I said that question would be decided when the case of Mr. Porter was decided. Now, if this amendment to the constitution prevails, you will not only cut off Mr. Porter and those applying for the benefits of active membership, but you will deprive gentlemen already holding active membership in the association, of that membership. Now, I ask you, is it wise to press the amendment? Was it wise to press an application for active membership under this constitution? I claim that Mr. Porter's business is purely that of electrical supplies; that he has no interest in electric lighting other than his parallel interest in articles consumed in electric lighting. If Mr. Porter had a plant where he was employing an engineer to take care of his plant, it would be necessary to send that man here to give such information as might arise in the discussion. He runs one light. There is no information which Mr. Porter would carry home that he would apply to the light, but he would apply it to the carbon business.

Digitized by Google

All these things make it unwise to force on this convention a questionable right to active membership."

Mr. Fishback—"I would like to know why Mr. Wadsworth is left on the other side of that line. Why is Mr. Wadsworth interested any differently from those other carbon factories that have as many lights?"

Mr. Morrison—"Mr. Wadsworth was operating a plant sufficiently large—this was the representation at the Chicago meeting—to make it desirable for him to seek information and to carry it home as regards the economical method of running electric lights; not to apply it in his business of carbon dealer, but to apply it in the electric light part of his business. Mr. Wadsworth was an active member of the association, elected as such at Chicago, and he brings his active membership here. If the amendment Mr. Leggett proposed prevails, Mr. Wadsworth ceases at once to be an active member."

Mr. Fishback—"At the convention at Chicago our claims were made and recognized. Yet to-day, in calling off the names, our company was omitted from the list. I intended to press the matter in a quiet way, but as long as it has been brought up, I would just like to know the reason, that is all. We are running a plant which is, I think, equally as large as the Boulton company's, and use it to light our factory at night."

Mr. Wadsworth—"When I became an active member of this association, I said I represented a plant. I do. I represent 35 lights, composed of about four different systems. Now, so far as myself being an active member of this convention is concerned, it is immaterial to me. It would make no difference to my business whether I was an active or associate member, but in the interest of other men, mill men and others, whom I know to be largely interested in this electric lighting business—men who have got two dollars for every one invested in this business by a great many members on this floor—I say that it is wrong that we make false promises in order to get what men in here we have got here representing certain private plants; and if we pass this resolution depriving them of active membership, they will not come here."

Mr. Morrison—"If I give the association the result of Mr. Wadsworth's special pleading, it will perhaps throw some little light on the subject. After he and the other gentlemen have been engaged in advancing the interests of the association throughout the United States, we have *one* mill represented in this national association—one mill—that is the Riverside Mill. I do not think, therefore, that that will affect the result."

Mr. Leggett—"I think the line should be drawn just where it was originally intended that it should be drawn, and to rule out companies, who are simply operating private plants, from active membership, and to include in the association just what was doubtless originally intended to be included—companies, firms or individuals who are operating plants for the purpose of furnishing light, renting lights, for private or public purposes. Now, there is a reason in this. Take the action of our executive committee as reported to-day upon the subjects for discussion before this convention—the feasibility and costs of underground wires, for instance. What has a private individual, operating an electric light for his own purposes, or a mill having a private plant—what interest have they in a subject of that character? Now, take another subject—the advisability of tower lighting in preference to pole lighting. You might take each subject right straight through that was named by our president to-day. Every one relates to that kind of matter which pertains to the public lighting plants. Now, it is a matter of very great concern to the lighting companies in this country to know about these things, and to organize themselves together into an association; and it seems to me that on matters which require a vote, on measures to be adopted, that those companies should not be trammeled in any way by the votes of parties, or individuals, or firms, or corporations, which are not interested in this matter of public lighting or renting electric lights. All these gentlemen are welcome here. They can get their $10 worth of information. This association invites them to speak on a certain subject. They are present to be heard, and they are present to hear. They can get all the information they seek, and we can get the advantage of their experience. But when it comes right down to a vote, upon matters which affect our interests as parties who are renting electric lights; as parties who are governed by municipal legislation, required to go underground, and required to go over ground; as parties interested in tower or pole lighting; when we are to have ourselves subjected to a vote by a party who has no interest in those things, no interest in common—that is, in those respects—it seems to me it is out of place."

Mr. Wadsworth—"I would like to ask why the manufacturers of electric lighting apparatus are not excluded. If you are going to exclude manufacturers of other supplies, why not exclude them? I would like to ask that as a matter of information."

Mr. Morrison—"Perhaps Mr. Leggett can answer that question. I know no reason why they should not be excluded."

Mr. Leggett—"I should say simply this, that we are dependent on that kind of thing. That comes right home to us. It is not so necessary with carbons. Carbon is in the nature of supplies, but when we come to purchase our supplies—when we want the thing made in this way or that way—those people are people who ought to be among us."

Mr. Bowen—"I agree most cordially with Mr. Wadsworth in the idea of putting a liberal construction on the membership of this association. We need the moral and pecuniary support of every man who operates an electric light, in my judgment. There are very few men operating electric light plants but can give us some information that would be valuable to us. With that thing in mind, I move that the whole subject be laid on the table, and that the constitution remain as it now is." The motion to lay on the table was lost.

Mr. King, of Baltimore—"I would propose that this matter be referred to a committee (of which I shall not be one) of three, to be presented to this association at some future time. It does appear to me, sir, that this is a very important matter. I look upon this as an association calculated to advance the interests of the electric lighting of the world. I believe, sir, that it can be such an association. If you admit all without any regard to their knowledge or attainments on the subject of electric lighting, you will have an unwieldy, large association. If you limit the active membership to those who are actively engaged in important matters of manufacturing plants, you will then be able to keep it in strict bounds; and, sir, is there any one here that would pretend to say that any gentleman who is interested in the electric lighting would not receive the value of $10 a year? I think not, sir. I think that the man who is engaged in running a very few lights will get a great deal more than his $10. For my part, sir, I do feel an interest in lighting, as you well know, and it was with a great deal of pleasure and anticipated information that I came here, and I yet expect to hear a great deal and to be amply repaid; and, therefore, I make the motion to refer this matter to a committee of three, in order that it may be presented at some future time." This motion prevailed, and the chair appointed as the committee Cooper, of Brooklyn; Leggett, of Detroit, and Weeks, of Kansas City.

Mr. Bowen—"There is at present in this city and Brooklyn an electrical commission. It seems to me it would be very proper to invite them to be present at the deliberations of this convention, and I therefore offer the following resolution:

Resolved, "That the Electrical Sub-ways Commission of the cities of New York and Brooklyn be invited to attend this convention, and be accorded all the privileges of the floor."

The motion was adopted, and the convention adjourned to 10 A. M., Wednesday.

WEDNESDAY—AUGUST 19.

The committee appointed to report on the amendment of Article 2 of the Constitution, submitted the following, which was adopted: "Members of this association shall be persons, firms or corporations engaged in the lighting business, to wit: that of supplying electric lights from a station to public or *private consumers*, as distinguished from such as are operating private plants, or engaged in the manufacture or sale of electric machinery, apparatus or supplies."

The last sentence in Article III. of the constitution was, on motion of Mr. Leggett, amended by substituting the word "consent" for "request" so as to read as follows: "Such associate members shall pay the same dues as members; shall be entitled to seats at all meetings, but have no vote; shall be ineligible to office, and shall be entitled to the floor only with the consent of the executive committee or presiding officer."

On motion of Mr. Weeks the following article was added to the constitution:

"Applications for membership shall be made to the president, and by him shall be referred to the executive committee, and they shall have power to act thereon."

A resolution was offered by Mr. Ridlon to the effect that a committee be appointed to consider the question of the necessity of the maintenance of uniform prices by the several manufacturing and lighting companies for all electric lighting apparatus and supplies.

Objection being made to the proposed legislation on the ground that it was impracticable, Mr. Weeks, of Kansas City, explained that it was intended more as a committee of conference than one of power. Competition in many cases had resulted in a general slaughter of prices, reaching in some cases but half the cost of production. He was of the opinion that the committee might in many cases exert a beneficial influence.

Mr. Cleveland, of Hartford, said that of course no committee could secure a combination. This question really illustrates the communion of interests between the manufacturing companies and the sub-companies. When a respectable company is running a service it is not fair for another company to come into competition with it with the result of making the stock worthless. This association should try to create a sentiment of fair play and a free field. Our company (the Schuyler) does not propose to engage in a cut-throat business. We have been invited to engage

Digitized by Google

in competition, but have declined. We have a good system, and propose to cultivate virgin soil, believing there is room for all. In thus treating each other fairly we at the same time make our property a desirable investment.

The resolution was adopted, with the proviso that the committee be made up of one member from each system represented in the association.

Mr. Bowen then spoke in his most pleasant vein upon the superiority of the electric light over any other illuminant for public lighting. In the lighting of the public streets and large buildings there was no other light produced at so small an expense that produces such desirable results. For interior lighting where sub-division was required, of course the incandescent system was preferable. He looked forward to the day when its use would be general. Any innovation of this character will certainly meet with more or less opposition. In a western district with which he was familiar, five or six local gas companies had formed a syndicate, and every item which is considered discreditable to the electric light is, through its influence, spread broadcast through the daily press. He suggested that the electric light interests unite with a similar object in respect to the destructive nature of gas. He thought that every village of over 1,000 inhabitants would yet be supplied with the electric light. To-day, in the city of Chicago, several hundred men are employed to light and extinguish the gas lamps at a cost of $90,000 per annum, the whole expense being $320,000. The time occupied is forty-five minutes. Detroit, with its electric tower system, is lighted up by the simple turning of a switch. Mr. Bowen concluded as follows: "When Franklin succeeded in his efforts to control the lightning with his kite, the goodly people of Philadelphia thought him possessed of evil; now we cook our tea, run sewing machines, operate railway trains, light our Hell gates and our great light houses, send messages around the world, heal the sick, print our newspapers, make our homes and business places cheerful, and by its beautiful and brilliant effulgence illuminate our cities and villages, and yet we have only commenced the utilization of this subtle and wonderful force, that cannot be analyzed by the chemist, dissected by the surgeon, nor weighed by the grocer.........Again, give us the highest civilization we can enjoy; give us sound and healthy bodies; give us no more darkness, but give us light! More light! Give us the electric light. It is the poor, as well as the rich man's light. It will light the suburbs as well as the central portions of your cities. It is, in fact, the light for all."

Mr. A. F. Upton, of the Jarvis Engineering Co., followed with a paper upon the subject of power. This he considered the most important question connected with electric lighting. The cost of power was usually computed on a wrong basis. The point was to get the actual cost of running each lamp per hour. The first question was fuel. It had been decided that the most economical manner was to belt direct to the dynamo. The central station at Brockton, with the Edison system, was fitted up with a plain steel tubular boiler 6x16, having 140 three-inch tubes, 120 h. p. engine, 150 h. p. run at 80 lbs. pressure, cutting off at ¼. It supplied from 1500 to 1900 16 c. p. lamps. Their experience showed 22 per cent. in favor of bituminous coal, using waste material, wet or dry.

The lowest cost station within his knowledge was that of the Thomson-Houston system at Lewiston, Maine, which was run at a cost of $.002 per lamp, per hour for fuel only. The usual average was $.004 per hour, using screenings and soft coal. In fitting up stations it was well to remember that from 10 to 15 per cent. of the power was consumed in driving the shafting, and he had known it to run as high as 22 per cent. He knew of a station in New York city which was suspended two weeks on account of breaking a line of shafting. These were some of the objections to arranging stations in this manner. In the city of Lawrence, Mass., the Edison system was driven by two 12x12 70 h. p. engines. Four circuits with 10 miles of wire were operated, supplying 500 32 c. p. lamps at $650 per month. The letting of power was a subject worthy of consideration. Large numbers of motors could be let ranging from one-half to five h. p., paying a good profit. At the Thomson-Houston station in Brockton, Mass., a shoe factory was located on the upper floors to which power was supplied during the day, from which an additional revenue of $2,000 per annum was derived from a 35 h. p. engine. It was a curious fact that the starting of the Edison electric lighting system increased the sale of gas, and after the arc system was started the increase amounted to 10 or 15 per cent. Every gas company in Boston reports an enlarged consumption of gas since the advent of electric lighting. The Harrisburg, Pa., incandescent system with wires all overhead had paid a profit from the start. Contracts for lighting were made by the year, payable monthly. The cost of the fuel used was but 89c. per ton, being screenings from soft coal.

As a rule, Mr. Upton said, water power had been abandoned as being too unreliable. At Manchester the water had been very low at times, while at Lewiston and Holyoke the service had actually stopped at times on account of failure in water power.

Mr. Winchester, of Holyoke, said that his company was using a 30-inch turbine wheel with a capacity of 120 h. p. The price paid to the water company was $400 per year for day and $150 for night service per mill power, which was supposed to be equivalent to 80 h. p. It averaged perhaps about 70. The cost of water only, after the fitting up of the machinery, was about $1 per day. The plant consisted of 103 Schuyler lamps for which they received 50c. per night for single lamps, and 65c. for all night service.

Mr. Jepson, of Norwich, Conn., said that with a plant of 55 arc lamps, the cost of fuel per lamp per hour was $.004. Their monthly coal bill averaged $34, the lights running 7 nights per week, 6 hours. The company pays 2 per cent. quarterly dividend.

Mr. Ridlon, of Boston, stated that with 600 lamps in use, he used an average of three pounds of coal per lamp per hour, at an average cost of $3 per ton. His carbons consumed cost more than the coal. He wished to make it perfectly clear, especially to the representatives of the press, that the discussion had been confined simply to the one item of cost of fuel. There were numerous other items of cost which should be taken into consideration.

Mr. Sperry, of Chicago, said that there were large stables for car horses near their station, and that they had arranged to use refuse from this source. The horses being bedded down in shavings, the manure being used in the proportion of five parts to one of coal costing $1.60 per ton made satisfactory fuel. Special arrangements were required to burn it, a blast being necessary, also an additional fireman. A similar plan had been adopted at Minneapolis.

Mr. Weeks said that the cost of coal was of importance, and also the employment of competent engineers and firemen. Especially was it necessary that the fireman should understand the principles of making steam. Their boilers had been set about 28 to 30 inches above the grate. They had raised them to 36 inches and the result had justified the wisdom of the change. Their lamps were run from dusk to daylight at an average cost per hour per lamp of $.003 for the fuel used, which was bituminous slack, at a cost of five cents per bushel or $1.50 per ton.

Mr. Upton remarked that throughout New England the cost of coal used averaged from $2 to $2.50 per ton.

Mr. De Camp, of Philadelphia, referring to the question of direct *versus* indirect belting, said that their experience had led to the adoption of a 24x48 Corliss engine as a matter of economy. This engine drove 16 dynamos. They had one line of 66 feet of 6 inch shafting, with eight No. 8 dynamos, another line of 40 feet, part 4½ and part 3½ inch shafting, also eight dynamos, four of them, however, being number sevens. Objections had been made to the system adopted on account of the loss of power by friction. The actual loss, however, in excess of direct belting was less than seven per cent., while they felt that they could stand ten per cent. By this plant 800 lamps can be run, while it can be used economically for as small a number as 150.

The president, Mr. Morrison, said that the experience at the Philadelphia station had done more than anything else to settle the question of large *versus* small engines. His experience in Baltimore had also been in favor of large engines where there is the work to be done.

Mr. Officer, of Council Bluffs, Ia., sought information as to what was wrong about his plant. He was not sure whether it was the quality of the Iowa coal, or the fault of his engine, furnace or boiler. He was, however, consuming as high as fourteen pounds of slack coal per horse power, or nine pounds of pea coal. Its cost delivered at his boiler room was $1.57 for slack and $2.02 per ton for pea, the result being 34c. per ton in favor of the latter.

Upon resuming his seat, Mr. Officer was overwhelmed with suggestions as to changing his engine and raising his boiler.

His copious note book was well filled with valuable hints, and as Mr. Bowen subsequently remarked, the information which he would carry back with him would be worth ten times the cost of his trip.

Mr. Kerr, of Westinghouse, Church, Kerr & Co., stated that the quantity of coal consumed per square foot of grate surface was important to know as it was frequently the case that fuel instead of giving out the proper proportion of heat by thorough combustion, was simply distilled and its energy wasted.

The convention then took a recess until 2 P. M.

Upon reassembling, Mr. Leggett, of Detroit, read a very interesting paper upon the question of tower lighting *versus* pole lighting, based principally upon his experience with the former system at Detroit.

This, he said, was probably the best example in existence of tower lighting. The systems of street lighting had been based on the illuminants used. Gas was of moderate illuminating power, hence to have located such lamps at a height of 100 to 200 feet would have rendered them useless. There were in Detroit 2,600 street intersections. This would require as many lamps, which at 50 cents per night would cost $1,300. The tower lighting is more satisfactory than any other system. It produces an artificial moonlight effect, and walking or driving by night is possible without constant apprehension as to obstacles ahead. Teams coming from an opposite direction may be distinguished

Digitized by Google

readily a block away. Not only the streets, but alleys and back yards are satisfactorily illuminated.

Union City, Indiana, in 1880, was the first place to introduce tower lighting, followed by Akron, O., and Cleveland, O.

John S. Adams, of Elgin, patented the skeleton tower which had now superseded the use of masts. Of these 200 had been sold and were now in use.

Detroit is a city of from 160,000 to 180,000 inhabitants. Its business section occupies about one square mile. Around this was a belt about one mile in width forming the residence portion of the city. Formerly 3,782 gas and naphtha lamps had been used, while large areas amounting to two square miles were not lighted at all. Not a single gas lamp was now in use. In 1884 the Brush company sought and secured the contract for lighting the city with the tower system at $95,000 per annum, for 66 towers of 100 feet, and six of 150 feet with 290 lamps. The company, however, erected 90 towers. In 60 days after the contract was executed, the towers had been built, the lines erected, and the city was lighted by the new system. The towers are located from 1,000 to 1,200 feet apart in the central portion of the city, and arranged triangularly; in the residence portion the distance is increased to from 1,500 to 2,000 feet; and in the suburbs from 2,500 to 3,000 feet. The total area lighted is about 10½ square miles. Detroit is now generally spoken of as the best lighted city in the world.

Evansville, Indiana, is lighted by 10 towers. During a recent cyclone, houses (both brick and frame) were destroyed, large trees torn up by the roots, and church steeples blown down, but the iron towers stood the test, not even a rod being bent. After this severe test, it is believed that nothing short of an earthquake can disturb them.

The gas companies made a bid to light Detroit at $40,000, but the Brush company secured the contract at $89,300. So bitter was the feeling against the possible return to the old system that in some sections the residents cut down the old naphtha lamp posts in order to prevent their use.

The most effective height at which to place the lamps was from 150 to 175 feet. After the latter elevation had been passed the lights gradually lose their power of illuminating the surface below. Five or six 2,000 c.p. lamps on the central towers and four on each of the others are used.

For a city of 12,000 inhabitants a central tower would be required with others placed at distances of 2,500 feet. A village of 5,000 inhabitants would require but a single tower. The total number of lamps used for lighting Detroit is 382, of which 24 are on poles; the latter, however, not being actually necessary.

In reply to a question by a member, Mr. Leggett said they had experimented with reflectors placed over the lamps, but could perceive no benefit from their use beyond protecting the lamps from the effects of the weather.

The breakage of globes was equal to the cost of fuel. A triangular frame had, however, been devised which could be fitted with ordinary flat glass, which, when broken, could be readily and cheaply replaced.

Mr. Bowen here read a despatch from Seneca Falls, N. Y., announcing that the tests of the 50,000 c.p. lamp recently erected there to light the town had not proved satisfactory, and that the use of kerosene would be resumed.

Dr. Otto A. Moses then addressed the convention upon the subject of "Incandescence." He was listened to with marked attention, and the gentlemen present who were principally interested in arc lighting apparently gathered from his words some ideas which were wholly new to them. Dr. Moses spoke substantially as follows:

"You have reached a point in arc lighting from which for some time to come we are not to expect very much improvement. You have been able to struggle against your common enemy, gas, and when you have eliminated it from the streets of the cities of the United States, you think the time has come for you to eliminate each other. Now, incandescent lighting has reached that point of development where in many places it has been able to compete with gas, and with arc lighting. If you examine the most remarkable installation of incandescent lighting in the world, the one bounded by Broadway, Wall street, etc., in the city of New York, you will not find one arc light running from the central station which supplies that incandescent light. And why? For the reason that it is a bagatelle. The amount of light that would be consumed in the streets in that incandescent district is so small as to be unnoticeable. You may say that it is a very large amount of money to expend in a small area, and for that reason they have taken a territory which in no way competes with the arc lighting company, and therefore their fields are distinct. The statement which I make is based on statistical observation. The street lighting of the city of New York is about five per cent. of the total lighting of the city, but in smaller towns the percentage is not more than three. The gas companies care very little about the street lighting, and oppose it principally to prevent the electric light from gaining a foothold. So you see that when you have conquered the whole field you cannot encroach on the field of the incandescent lamp. You will find that when you have the whole thing, it amounts to about five per cent. Who have the rest? Our common enemy, the gas companies.

"If electricity is to prevail as an illuminant, it can only be by means of the incandescent light. Now, then, since the arc lights have reached a point of perfection, we will consider why they cannot extend their domain. In the first place, arc lights have reached a certain point of the development where the elements of light giving are fixed; a certain amount of electromotive force, almost a standard, an arc varying from an eighth of an inch to half an inch; a standard of carbon—perhaps of seven-sixteenths of an inch average—all these things are fixed. The length of line, attendance, cost of carbon, breakage of lamps, all these things are fixed. You cannot get any more light out of an arc lamp than you are getting to-day. You will get, as Mr. Bowen remarks, 50,000 candles; you may get a quasi 2,000. Now, in comparing an arc light and an incandescent light, you will find that an arc will give a great deal more light for the fuel consumed, I think you may say five times as much light as an incandescent light, for the fuel. But every one will admit that through the consequent sub-division of light in the incandescent light you get what is more than commensurate. As to the cost of supplying carbons, that is more than the cost of supplying the filament for the incandescent light, so that we can eliminate that. We come, laying aside the first investment, to this fact, that you can get five times as much light per pound of coal consumed, in the arc light than you can in the incandescent light. But I think you will all admit that you are not going to get any more out of your arc lights. That has reached its limit. The problem is simple and has been solved. Now, where is the limit of this fledgeling incandescent lamp? The incandescent lamp that was used in the beginning of 1879, the experimental lamps of Sawyer and others, were not economical at all; they used large conductors in vacuo, but the vacuo was imperfect. Finally, in one great step, the world saw in 1879 and 1880 a sudden departure in the mechanism of incandescent lamps. The principles all existed. They were known since 1846, from the time of Starr, who took out a patent on the incandescence of carbon in vacuo. His vacuum was very poor, and his carbon was a thick rod. In 1879 incandescent lighting, after a very long gestation, was born. We have to-day an infant seven years old that I think is going to strangle gas with one hand and petroleum with the other. That infant is a very robust one. He is to-day competing with a very well-developed man. He is competing with arc lighting. He is also competing with gas lighting. And is he to stop his growth in his seventh year? I think that is asking too much of him, particularly when he has in New York and elsewhere, some very good foster-mothers, who are supplying him with all the experimental food that he may need, and he is gradually developing and will continue to develop. But as he is he can hold his own in competition with gas and arc lighting to a certain extent, an extent that implies his great development. Now, what is he going to be in the next seven years? Let us see where his elements of progress lie. Let us consider the limit to begin with. We find that the incandescent lamp, as it exists, is a very small filament of some hydro-carbon substances. You find Cruto, in Italy, making a carbon much smaller than is now used, piled up by deposition from gases. He takes a material that is already an excellent conductor of electricity, and deposits his carbon on it, and then he builds up a perfectly solid and homogeneous material that produces a wonderful economy. It costs a good deal, but that is nothing. The first lamps cost $150 each. The day will come, gentlemen, when you will see carbons made just as easily as thread is made by the Willimantic company. It is simply necessary to time your deposits. Now, when that can be done, and that is simply a matter of mechanical ingenuity, you will get, instead of the present economy of nine 16-candle lamps or ten 16-candle lamps, 30, 40 or 50. I will take a carbon to-day, and bring it to a point of incandescence where it will represent one hundred. That is a question of fineness of carbon. I have succeeded in making filaments as fine as the web of a spider. The life of the lamp has to come from other matter. That is the result of experience and the integral character of the material employed. When that day comes, the death-sentence of gas has been passed. It is simply a question of burning coal under boilers. To-day the cost of the incandescent lamp is less than one mill per hour. You, gentlemen, spoke of exceptional cases of arc lights being run at a cost of two mills. Give me the coal to burn under the boiler, and one mill will be the only cost of the incandescent lamp. Give me plant and coal and fixed capital, and the other is simply a matter of the cost of the lamp, which is at the present prices simply one mill per hour. This is based on the life of one lamp at one dollar for one thousand hours. The subject is an endless one, and you will excuse me if I retire and allow others to speak." [Applause.]

The president complimented the speaker upon the extremely instructive and interesting character of his address, and admitted that the arc light must stop at the door of the dwelling, or of the hotel, excepting the lobby, but thought that it was entitled to a little more than 5 per cent. of the lighting business. No one would permit such a lamp in his bed-room, for instance; it

Digitized by Google

would be worse than a first-class case of the "jim-jams." He thought that the arc light had reached a point at which it became a business success. "I take it," said he, "that every man in this room, because you are all thinking and intelligent men, will have carried away a 'bee in his bonnet' that will keep him thinking for some time to come. When I say 'we' I mean the men who have their brains and their money both in electric lighting, and are eternally searching for something that will be of a greater commercial value than what we now possess. We are looking forward to the time when we will have these promises redeemed in the incandescent field. I believe the near future is pregnant with great results in the field of electric lighting. We will wait for that. We will let the gentlemen who have started experiments keep them up until we get along to a point where we can make money."

Mr. Holt of the Brush company, Cleveland, addressed the convention on the subject of arc and incandescent lamps on the same circuit. He said: "In Grand Rapids, Mich., the Thomas cut-out is used, and reported highly successful. The system is one to which any kind of incandescent lamp may be adapted. The lamps are arranged in groups. The system run by the Brush company embraces seven groups, connected to their 2,000 candle power circuit. In connection with each group, is put in what is called a multiple series cut-out, and so arranged that if one or more of the lights should go out, this cut-out operates either to short-circuit the group and extinguish the rest of the lamps, or in some cases to throw in a resistance equal to the number of lamps cut out. Or in other cases to throw in a resistance which is somewhat less than the working resistance of any of the lamps, consequently, the remaining lamps are dimmed only. Of course the cut-out is better for the general circuit, but with the other, the lights being simply dimmed, the consumer is not deprived of all light. He can immediately tell which lamp has failed. You can readily see that this system can be adapted to almost any circumstances, except those of house lighting. We do not recommend it for house lighting, because there is a well-founded prejudice against introducing high tension currents into houses. But for stores, offices, hotels, and all places where people prefer the incandescent light to the arc light, it is a system that is beautifully adapted."

A brief general discussion ensued, which tended to confirm the wisdom of the Brush company in not recommending the general adoption of a mixed system, as it was evident that the fundamental principles of electrical distribution were not sufficiently understood to warrant the promiscuous introduction of incandescent lamps upon arc circuits.

At 5 P. M. the convention adjourned until the following day.

THURSDAY—AUGUST 20.

The location of the next meeting of the Association was the first work of the day. The city of Baltimore had been selected by the executive committee, and the time fixed for February, 1886.

Mr. Wadsworth, of Cleveland, with an eye to the geographical fitness of things, ever mindful of the fact that Ohio is the heart of the country, suggested that as the first convention was held at Chicago, and the present one as far east as New York, it would be wise to select a more central point. Modesty appeared to stifle the suggestion that Cleveland was the spot—he hesitated and was lost, for the ever ready president reminded the members that we were yet in the early stages of the new Democratic administration; that Congress would then be in session, and he believed that a majority of our citizens would have business in Washington at about that time, and it would be necessary for them to pass through Baltimore. In fact, it was hardly possible to get anywhere without going through Baltimore.

Sundry remarks as to the well-known hospitality of the genial president, the superiority of the oysters and terrapin, neutralized all further objection, and the action of the executive committee was confirmed. A committee on transportation was then appointed, consisting of Messrs. Wadsworth, Weeks, Bowen, Ridlon and Cleveland.

A resolution was adopted officially locating the headquarters of the Association at Baltimore, Md., to be a repository of all information pertaining to electric lighting and kindred topics, and also that correspondence be solicited with all home and foreign associations.

A committee was appointed consisting of R. W. Pope, of the ELECTRICIAN AND ELECTRICAL ENGINEER, W. J. Johnston, of the *Electrical World*, and George Worthington, of the *Electrical Review*, to select the names of prominent electricians in foreign countries, whom they might consider as worthy candidates for honorary membership.

E. A. Sperry then presented a valuable paper upon "The Best Form of Dynamo," illustrated by blackboard diagrams. (See page 324.)

Mr. Spang, of Reading, who had been listening attentively to the points brought out by Mr. Sperry, arose to demonstrate that the Ball dynamo was the proper form, but he was reminded by the president that the respective merits of different varieties of dynamos were not proper subjects to be brought before the convention. Debate must be confined to the general principles which were common to all.

Mr. Spang, resuming the floor, continued his remarks, guided by the cautionary advice of the president, and after mentioning the severe tests which the unipolar dynamo had undergone in the new Croton aqueduct work, he introduced the following resolution, which was adopted:

Resolved, "That a committee of three be appointed, who shall send a communication to each company manufacturing dynamos, requesting them to submit a 5–10–15 ampère machine, capable of producing not less than 30 arc lights, and an incandescent machine capable of producing not less than 200 incandescent lights, within one year's time, to the association, to be tested by them."

Mr. F. J. Sprague, of New York, followed, and demonstrated by diagram and formula the correctness of Mr. Sperry's theories.

Ralph W. Pope, of New York, followed with a paper upon the subject of "Placing Wires Underground." (See page 334).

George H. Benjamin, of New York, stated that he had made the subject a study, and had made many experiments in connection with Dr. Siemens. He was fully convinced that the most satisfactory system must be an underground conduit in which the wires were to be placed bare, and from which they could be removed if necessary. He believed that no difficulty would be experienced in burying the wires, and that we were being frightened by a bugaboo. The cost of placing the wires underground was about 30 per cent. more, but the subsequent repairs would cost 150 *per cent.* less.

Mr. Sperry said his company was operating about two miles of wire underground, and that his experience was that it was expensive principally on account of the troubles which occurred where the wires passed through the area ways. It was his company which operated a 42-light plant the wires for which were naked, and ran through the tubes in the manner described by Mr. Pope. This was merely an experiment to test the insulating quality of the conduit, which thus far had proved satisfactory. The wires were not introduced as conductors, but were intended for eventual use as draw wires.

Mr. De Camp was of the opinion that the expense of maintaining overhead wires had been very much exaggerated. He happened to have with him a memorandum of the cost of maintenance for seven months of 67 miles of overhead wire. The average is $\frac{17}{100}$ of a cent per day per lamp.

The president (after sundry questions and a little figuring) said: "It appears Mr. De Camp takes care of his wires for about $1.36 per day, He must have one lineman, at about $10 per week. Now this is a pretty important matter for some of us. If my directors find out what it costs Mr. De Camp to maintain his wires, I shall find a great big club in soak for me when I get home. I want this explained. Does not the city furnish the poles?"

Mr. De Camp—"Yes; they keep up the poles, and their renewal is not included in these expenses; but we paint the poles, and would be glad to have our own."

Mr. Curtiss, of Cleveland—"I would like to ask Mr. Benjamin that if he had his money invested in electric lighting, he knew of any underground system which he would recommend to place his wires in."

Mr. Benjamin—"I would answer that by saying that I do not think I would put my money in the electric lighting business. However, if I was in a position where I could supply 600 subscribers, I would put down a lead-covered cable."

Mr. Holt—"It appears to me that if the electric light companies were required to erect a straight line of poles, having say electric light wires on the lower arms, telephone wires above, and telegraph wires still higher up, occupying both sides of the street, that most of the objections to overhead wires would be overcome."

W. O. Callender, London, England, followed with a few remarks regarding insulation underground. He said that during the past year the increase of incandescent lighting in England had been extensive, while the arc system is gradually disappearing. With the exception of those used at the railway stations he did not believe there were more than 500 arc lamps in use. An insulation for underground use must be a material which is unaffected by drouth, dampness, the earth, sewer gases, or escaping illuminating gas, with which the ground in large cities is thoroughly impregnated. "After many years' experience with bitumen in making asphalt for paving purposes, I found that it was practically indestructible. In 1869 I laid down a very large work in London and recently took up some samples, which upon comparison could not be distinguished from pieces directly from the factory. After experimenting considerably with a view to making it plastic, I succeeded in producing a substance which I call bitite." (Mr. Callender here exhibited a series of plans for placing wires underground.) In reply to a question how he would lead a loop from the interior of a mass in which the wires were solidly imbedded, he said that the plan shown was prepared at the request of the United States and Brush companies,

Digitized by Google

to show how trunk wires would be carried from one point to another where they would not need to tap them.

After a brief discussion, during which Mr. Callender made further explanations of his plans, the president announced that the hour of adjournment having arrived, he would briefly thank them for their courteous treatment of him, more especially as their only rule of government was the gavel. Having then announced the appointment of the following committees, to which additions would be made from time to time, he declared the convention adjourned.

COMMITTEES.

Conference Committee on Uniformity of Prices for Apparatus and Service, Frank Ridlon, Brush-Swan, Boston; Charles Cooper, Thomson-Houston, Brooklyn; George S. Bowen, Van Depoele, Elgin; W. A. Chase, Schuyler, Holyoke; C. B. Ver Nooy, Sperry, Chicago; Mr. Lyne, Ball, Jersey City; A. L. Ide, Fuller, Springfield, Ill.; A. J. DeCamp, Brush Electric company, Philadelphia; Thomas Smith, Ft. Wayne, Jenney, Peoria; George D. Guernsey, Excelsior, St. Louis.

Electricity as an Illuminant, Messrs. Bowen, Chicago; Moses, New York; Sperry, Chicago; Cleveland, Hartford; and Holt, Cleveland.

Proper Construction and Maintenance of Wires, Messrs. A. J. Holt, Cleveland; A. J. Dalzell, Hartford; P. Fahay, Boston; S. A. Duncan, Pittsburg; E. R. Weeks, Kansas City.

Steam Power, Messrs. Ide, Springfield; D. E. Evans, Baltimore; De Camp, Philadelphia.

Underground Lines, Messrs. Ralph W. Pope, New York; E. A. Sperry, Chicago; W. R. Patterson, Chicago.

Incandescent Lighting, Dr. Otto A. Moses, and others.

History aud Progress of Electric Lighting, George Worthington, *Electrical Review*.

History and Progress of Electricity as Applied to Motors, W. J. Johnston.

Electric Lighting in Canada, C. A. Ross, Montreal, Canada.

Measurement of High-Tension Currents, Best Instruments for, C. J. Van Depoele, Chicago; Prof. Thomson and E. J. Houston, of Philadelphia.

Best Equipment for Arc Lighting Stations, D. E. Evans, of Baltimore, and N. S. Possens, Cleveland.

Operating Expenses, E. R. Weeks, Kansas City; A. J. De Camp, Philadelphia; D. W. Guernsey, St. Louis; George O'Connor, New Orleans; E. H. Goff, New York; H. C. Tudor, Baltimore, Md.

Line Wire, Best for Overhead Lines, Size, Insulation, etc., H. M. Cleveland, Hartford.

Carbons and Globes, Frank Ridlon, Boston, and others.

Storage Batteries, A. J. Holt and George H. Benjamin.

Motors, Charles J. Van Depoele and Wm. Hochhausen.

Arc Lighting, Wm. Hochhausen.

The following named gentlemen were in attendance during the convention :

Angell, Fred.—American Electrical Works, Providence.
Adams, H. C.—Holmes, Booth & Haydens, N. Y.
Allen, George D.—Excelsior Co., Brooklyn.
Buckley, W. J.—Chicago
Baxter, Wm. Jr.—Baxter E. L. Co., N. Y.
Benjamin, Geo. H.—Constant Current Electric Storage Co., N. Y.
Baker, W. H.—American Electric Manufacturing Co., N. Y.
Baird, M. E.—Holmes, Booth & Haydens, N. Y.
Bowen, George S.—Elgin Electric Light Co., Elgin, Ill.
Beetle, George L.—Lytle & Co., N. Y.
Brintnall, H. L.—East Saginaw, Mich.
Blakeslee, G. G.—Benedict & Burnham Manufacturing Co., Waterbury, Ct.
Cleveland, W. B.—Forest City Electrical Works, Cleveland, O.
Candee, J. N.—Brooklyn, N. Y.
Callender, W. O.—Callender Insulating Co., Newark, N. J.
Callender, C. M.—Callender Insulating Co., Newark. N. J.
Carmen, Henry C.—Tesla Electric Light Co., Rahway, N. J.
Cleveland, H. M.—Schuyler Co., Hartford.
Cooper, Charles—Municipal Co., Brooklyn.
Curtiss, C. C.—Brush (parent) Co., Cleveland.
Coggeshall, Mr.—Mitchell, Vance & Co., N. Y.
Coughlin, W. H.—Worcester, Mass.
Condict, J. E. & H.—San Francisco.
Dam, A. J.—Hotel Dam, N. Y.
Donaldson, G.—St. Paul, Minn.
Dustin, Charles—Schuyler Co., Hartford.
Duncan, S. A.—Brush Co., Pittsburg.
De Camp, A. J.—Brush Co., Philadelphia.
Elder, J. S.—American Electric Manufacturing Co., N. Y.
English, James—Electric Light Co., New Haven.
Fayhay, P.—Brush-Swan Co., Boston.
Fishback, L. M.—Parker-Russell Carbon Co., St. Louis.
Guernsey, D. W.—Guernsey & Scudder, St. Louis.
Goff, E. A.—American Electric Manufacturing Co., N. Y.
Gilbert, F. H.—Electric Light Co., New Haven.
Garrett, R. S.—Southern Electric Co., Baltimore, Md.
Hill, J. M.—Chicago, Ill.
Hunt, W. T.—*Electrical World*, N. Y.
Harrington, F.—Western Electric Co., N. Y.
Hochhausen. Wm.—Excelsior Co., Brooklyn.
Holt, A. J.—Brush (parent) Co., Cleveland.
Hotchkiss, Clark B.—Day's Kerite Cable, New York.
Heap, Maj. D. P.—Secretary U. S. Lighthouse Board, Washington.
Ide, A. L.—Ide Engine Co., Springfield, Ill.
Jepson, Joseph.—Thomson-Houston Co., Norwich, Conn.
Jenks, W. J.—American Electric Manufacturing Co., N. Y.
Johnston, W. J.—*Electrical World*, N. Y.
Jones, O. L.—Domestic E. L. H. & P. Co., Boston.
Key, J. B.—Okonite Co., N. Y.
Kelly, J. F.—Electrical Supply Co., N. Y.
Kerr, Walter C.—Westinghouse, Church, Kerr & Co., N. Y.
King, F. W.—Brush Co., Baltimore.
Linnell, H. M.—Schuyler E. L. Co., Ill.
Leggett, W. W.—Brush E. L. Co., Detroit.
Lytle, H. B.—Lytle & Co., N. Y.
Libbey, A. L.—Globes, Boston.
Morss, Everett—Morss and White, Boston.
Moses, Otto A.—New York.
Mayo, George A.—Mayo Electric Co., Boston.
Morrison, J. F.—Brush Co., Baltimore.
Moore, John J.—Springfield (Mass.) Electric Light Co.
Millis, Lieut. J.—In charge of lighthouse experiments at Hell Gate and S. I.
Moore, Alfred—Wire, Philadelphia.
Martin, T. C.—*Electrical World*, N. Y.
Noonan, J. F.—Paterson Electric Light Co., Paterson, N. J.
Nicholson, Mr.—President Ball Engine Co., Reading.
O'Beirne, E. J.—Star Iron Tower Co., Fort Wayne, Ind.
Officer, Thomas.—Council Bluffs Electric Light Co.
Parker, George W.—Parker-Russell Carbon Co., St. Louis.
Porter, George F.—Pittsburg Carbon Co., Pittsburg.
Pope, Ralph W.—ELECTRICIAN AND ELECTRICAL ENGINEER, N. Y.
Price, Charles W.—*Electrical Review*, N. Y.
Ridlon, Frank—Brush-Swan Co., Boston.
Rolfe, Charles—Western Electric Co., New York.
Shippey, H. L.—J. A. Roebling's Sons Co., N. Y.
Stiles, A. K.—Van Depoele Mfg. Co., Chicago.
Sperry, E. A.—Sperry Co., Chicago.
Spang, H. W.—Ball Co., Reading.
Stanley, H. D.—Bridgeport Brass Works, Bridgeport, Conn.
Smith, Gilbert M.—Ansonia Brass and Copper Co., N. Y.
Sheriff, J. B.—Sheriff, Son & Co., Pittsburg, builders of high-speed engines.
Stump, C. E.—*Electrical World*, N. Y.
Sprague, F. J.—Sprague Electric Railway Co., N. Y.
Thayer, H.—Western Electric Co., N. Y.
Tuxworth, D. H.—Southern Electric Co., Baltimore, Md.
Upton, A. F.—President Jarvis Furnace Co., Boston.
Waring, R. S.—Standard Und. Cable Co., Pittsburg.
Weeks, E. R.—Thomson-Houston Co., Kansas City, Mo.
Winchester, R. C.—Holyoke (Mass.) Electric Light and Power Co.
Wadsworth, George—Boulton Carbon Co., Cleveland.
Wiley, George L.—Waring Cable, N. Y.
Worthington, George—*Electrical Review*, N. Y.
Wetzler, Joseph, *Electrical World*, N. Y.

AFTER THE ADJOURNMENT.

During the last day's session of the electric light convention a cordial invitation was extended by the Messrs. Callender to all the gentlemen present to visit their insulated wire establishment at East Newark, N. J., for which purpose a special train would be provided, leaving Jersey City Friday evening. There, might be seen a plant of about 50 arc lamps supplied through wires running over head, under ground, and under water.

As over 24 hours had intervened since the adjournment of the convention, the representatives from out of the city were not plenty. Mr. Thos. Officer, of Council Bluffs, Ia., was present, with a look of determination on his countenance, as if he was bound to gather a winter's supply of information before he left this city. New York and vicinity contributed a goodly number of visitors, however, and the waiting car on the Jersey side was quickly filled with about 50 people electrically inclined. The visitors were cordially welcomed at the factory, a brilliant spot in the surrounding gloom of a cloudy evening. Messrs. W. O. and W. M. Callender, manager Thompson and superintendent Henderson, each took charge of their respective quotas of "visiting statesmen," and pointed out the various stages of the manufacture of insulated wires and cables. The material is mixed in the basement below, and subsequently vulcanized in large ovens, the latter process requiring five or six hours. This part of the manufacture was temporarily suspended, it being kept secluded from the public gaze. The "bitite," as the compound is named by Mr. Callender, is next thoroughly masticated by running through a pair of heavy cutting rollers, after which it is passed repeatedly between two smooth rollers, by which it is rolled into thick sheets. These sheets being cut into strips, are fed into a die through the centre of which passes the wire, the bitite being closed in upon it, making a perfect covering. As this process heats the insulation, the wire as it leaves the die is led through a trough of running water about 75 feet in length, and it is thoroughly cooled. After this process the wire may be spirally wound with tape, covered with braid, or specially treated according to the requirements of the customer. All of the wire manufactured is thoroughly tested by being immersed in large tanks of water provided for the purpose, where the electrical measurements are conducted with the same care, and by the same methods as are used in connection with ocean cables. The testing room is very neatly and thoroughly fitted up with a reflecting galvanometer and accompaniments. The instrument table is formed of a slate slab supported upon an independent timber framework, passing through the floor and imbedded in masonry in the earth. Immediately adjoining, in a convenient corner, a well-filled table, ornamented with bouquets, riveted the attention of the guests, as they gradually assembled after their tour through the works. Sundry flowing bowls were observed, containing various liquids, nicely graduated to suit the tastes of a promiscuous assemblage. A pleasant hour was passed in this spot, when the announcement

Digitized by Google

of "all aboard" reminded the revelers that time was up, and the waiting train soon carried away a well satisfied company, comprising, among others, M. W. Goodyear, T. C. Martin, Clarence E. Stump, Joseph Wetzler, R. W. Pope, Wm. Hochhausen, Otto A. Moses, Thos. Officer, W. J. Jenks, E. M. Bentley, L. Stieringer, John Stanton, Dr. O. Lugo and E. T. Barbarie.

REUNION OF MILITARY TELEGRAPHERS AND OLD TIMERS.

WHILE resenting the intimation that he is growing old, the true "old timer" is proud of his bald head or gray hairs, knowing that they represent a record. It is eminently fitting that these organizations should blend harmoniously, for the telegraphers at home were scarcely less important in the service of the country, in those stirring days, than were those who bivouacked at the front—the clicking of whose sounders mingled with the din and tumult of battle, siege and skirmish.

When the meeting of the military telegraphers was called to order in this city at 11 A. M., August 19th, a beautiful steel engraving of General Grant, under which resolutions of sympathy and condolence were handsomely engrossed, was exposed to the view of the members. The work, although large, was finished according to the utmost good taste, and brought forth unanimous approval. The picture will be exhibited at future meetings of the society. President Plum's report was quite lengthy. He dwelt largely on the necessity of pressing for recognition from Congress in the shape of pensions, especially for those who are now suffering from diseases contracted by service in the war. Several urgent cases of destitution that had been brought prominently to his notice were cited. Twenty odd new members were then admitted to the association, and fitting resolutions on the death of General Stager were adopted. The treasurer's report showed a balance of $151.85 on hand. A message of sympathy was despatched to L. J. Kelley, of Painesville, Ohio, stating that it was with regret that the members of the association learned of his total blindness, which was caused by exposure during the war. An assessment of $3 was levied to meet any cases of want and destitution that may arise. By vote $500 was appropriated for congressional purposes. The old office-bearers were then unanimously re-elected. They are as follows: W. R. Plum, of Chicago, president; Col. J. R. Gilmore, of New York, vice-president, and J. E. Pettit, of Chicago, secretary and treasurer. After some desultory discussion and exchange of opinions and views, the convention adjourned to give the members an opportunity to attend the banquet, and, notwithstanding the heavy rain, the trip to Coney Island was an enjoyable one. Around the festive board in the Manhattan Beach hotel were seated fully 150 military telegraphers and old timers. Appropriate remarks were made by President Plum, James D. Reid, Thos. P. Scully and others, and toasts drank. A safe return to the Murray Hill hotel was effected at 1 A. M., by a special train, after an evening of thorough enjoyment.

Promptly at 10 A. M. on the following day, August 20, the meeting of the Old Timers was rapped to order by president C. W. Hammond, of St. Louis, who delivered an interesting address. Seventy-three new members were then elected—a suggestive number, as remarked W. J. Dealy. A communication and a photograph of James Leonard, from Chas. E. Taylor, of Frankfort, Ky., were placed, by vote, among the archives of the association. The treasurer's report showed a balance of $76.65 on hand. Old time reminiscence was then for some time indulged in by Mr. David Brooks and others, after which the convention adjourned to the steamer "Sylvan Dell," in the cabin of which a joint meeting was held, and many interesting communications read, including a poem by George Walcott, of New York. Mr. James D. Reid was unanimously and enthusiastically elected president by acclamation. Mr. C. S. Jones, of Chicago, was made vice-president, and W. J. Dealy, of New York, secretary. Votes of thanks to the retiring officers and to the New York committee of arrangements were passed. Cleveland, Ohio, was selected as the place for the next meeting. The association appropriated $25 towards the erection of a monument to the memory of James Leonard, to be situated at Frankfort, Ky. Mr. C. C. Hine, of New York, gave $25 for the same purpose, and other contributions were offered. The constitution was changed to qualify for membership any person in the business 20 years, of which time at least one year must have been devoted to manipulating the key. All points of interest on the East and North rivers and in the bay, including the Statue of Liberty, Riverside park, Governor's, Blackwell's and other islands, were visited. Commodore Wiman was on board, and personally looked after the comfort of his guests, who had now swelled to almost 500 happy old timers. Never was such a large gathering of prominent electrical men held, and the best of feeling prevailed throughout, and a hearty vote of thanks was given the commodore for his kind treatment. The delegates left for their homes the following day, taking with them the kindest remembrances of the generous hospitalities extended to them by the New Yorkers.

The next reunion of the organizations will be held at Cleveland, Ohio, beginning on the third Wednesday of August, 1886.

The following is a partial list of the gentlemen present, many of whom were accompanied by their wives, daughters, and lady friends, composing as bright and well-appearing an assemblage as can be brought together:

Atwell, J. W., Chicago, Ill.
Adkins, George, N. Y.
Brooks, David, Philadelphia.
Bradnack, Dr. Fowler, N. Y.
Burnett, Geo. A., Buffalo.
Buehler, Rich'd E., Greenville, Mo.
Bruner, Phil., Wellesville, O.
Burch, Chas. B., Chicago.
Barth, Martin, Gallatin, Tenn.
Bunnell, J. H., N. Y.
Bliss, A. H., Chicago.
Bates, D. H., N. Y.
Brant John, N. Y.
Brown, A. S., N. Y.
Bresee, H. Y., Binghamton, N. Y.
Chamberlain, H. B., Denver, Col.

THE BATES-FIELD-GARRETT-GREEN-PENDER CORRESPONDENCE.

The daily papers during the past month have been well supplied with copies of letters and telegrams, the object of which was to show whether Mr. Garrett did or did not make overtures for either an amalgamation or pooling arrangement between the rival telegraph companies.

In connection with this subject, the following extract from the Baltimore correspondence of the *Maryland Journal* will be found of interest.

BALTIMORE, August 21, 1885.

The commercial and business mind of Baltimore continues to be considerably exercised concerning Mr. Robert Garrett's recent tournament with Jay Gould, Russell Sage, Cyrus W. Field, and other money kings. The latter gentlemen of unblemished virtue and unimpeachable veracity, have been earnestly laboring together in an endeavor to prove that Mr. Garrett has offered to sell them the Baltimore and Ohio telegraph lines, for consolidation with the Western Union system. Mr. Garrett positively denies this, and therefore leaves floating around a lie of large magnitude, without any accurately defined paternity—an orphan lie, so to speak. While it would be difficult to assign any valid reason against Mr. Garrett's assertion, it is easy enough to see abundant cause for the action of the New York bandits. They are virtual owners of the Western Union, and have "watered" its stock up to the enormous sum of $80,000,000, while the actual value of their entire stock in trade is not one-fourth of that amount. Until the Baltimore and Ohio lines were established the Western Union held a practical monopoly of telegraph business in the entire country, having absorbed all lesser lines necessary to its vast connections. But the Baltimore and Ohio system has grown to be a dangerous rival, and has forced the Western Union to such a large reduction of rates as to prevent payment of dividends on its $80,000,000 of stock. As a consequence, Gould and his brother robbers find that they can save the life of their swindle in no other way than by getting possession of the Garrett line.

To attain such a vitally important end they will not hesitate at any needful amount of lying; and it is safe to assert that the present dispute as to veracity is due entirely to a fear of probable bankruptcy on the part of the Western Union. But, whatever be the cause, the imbroglio has had the excellent effect of opening the eyes of our people to the perilous magnitude of the operations in which the Baltimore and Ohio company is engaged out-

Digitized by Google

side of its legitimate railroad business. The state and city are large holders of the stock, and the subject is, therefore, of general public concern; but it is an open fact that our Baltimore newspapers have continually refrained from critical comment on the acts of the road's managers. In fact, since the passage of the Stockholder Direction bill, some 25 years ago, the company has been practically "a close corporation." State and city directors have been regularly appointed, but they may as well be wooden men for all they were permitted to know of the real operations of the direction. Once a year the stockholders and the general public have been given a report of the road's affairs, and the figures thereof were large exponents of increased traffic and corresponding profits. But the state, city, nor individual stockholders were never seriously consulted about the institution of a telegraph company, an express company, or the extension to New York by which Baltimore is to be made a way station. The unwisdom of this extension is generally confessed, chiefly on the ground that there can be no profit in its competition with a near and parallel railroad. The express business has no doubt been profitable, because its equipment was of but little cost to the railroad company. But the telegraph plant is a very different matter. Its cost has been enormous, and it is said that its receipts do not pay current expenses.

All this may or may not be true; but there certainly begins to be seriously agitated an inquiry as to the *right* of the directors to use the company's resources and credit for the purpose of antagonizing the Pennsylvania Railroad, Adams' Express Company, and the Western Union Telegraph. Perhaps the subject would not have been brought into discussion but for the fact that the question of veracity between Mr. Garrett and the Jay Gould bandits has given opportunity for statements which, whether true or false, are calculated to depreciate the value of the B. & O. stock, that for years has stood at so high a premium as to keep it out of the market. Naturally enough, the holders of it must be alarmed at Jay Gould's assertion that the B. & O. Telegraph is losing $500,000 per year, and that the company is heavily indebted to New York and New England banks. And this healthy alarm will probably be of benefit if it result in a combination of stockholders to compel the railroad direction to confine itself to the business for which it was incorporated.

SUBTERRANEAN PLANS SUBMITTED TO THE COMMISSION ON ELECTRIC SUBWAYS.

It was announced that August 13th would be the last day allowed for the filing of plans by the various electrical companies for future subterranean work. Nothing of a definite character was received, although promises were made to submit plans in the future. A large number of communications have been received from inventors and companies controlling patents for constructing a system of underground wires, and these have all been laid over for future consideration.

A communication was received from the New York Electric Lines Company submitting a plan for a trunk line of underground wires, to consist of four cast iron pipes running side by side, and intended to accommodate in one system all the wires of the companies doing business in this city.

The Hussey Electric Light and Power Company also submitted plans and a map of the system on which it is working, by which portions of the wires are laid underground and the rest on the face of the curb or along the angle formed by the curb and the pavement. Among other systems presented at subsequent sessions of the commissioners were the following:

The Universal Insulating Co. of Paterson, N. J., submitted a cheap insulating material for wires.

The Commercial Cable Co. described the plan adopted by it as a gutta-percha cable, drawn through an ordinary cast-iron pipe placed three feet below the surface. In the upper part of the city no pipe was used, the cable being protected by blue-stone flagging placed over it.

The Averell company sought information regarding the number of wires to be placed underground, in order that they might prepare maps and plans. The Department of Public Works was instructed to furnish such details as might be in their possession.

Mr. Heylyn submitted a sample of concrete composed of rosin, plaster-of-paris, sand, and oil residuum, of which he proposed to build a conduit of any pattern required. He was requested to furnish a model, which he agreed to do.

B. F. Carpenter, of Roselle, N. J., submitted drawings and description of an underground pipe or conduit three feet in diameter, with brackets along the sides and a railway on the bottom, upon which a lineman makes his tour in a reclining chair fitted with wheels.

George W. Mowbray presented samples of his insulated wire, the rubber used in its covering being mixed with naphthaline during manufacture, which subsequently evaporates, leaving the gum in a pure state. He stated that 1¾ miles had been placed underground for telephone purposes in Boston, of which a report had been promised, but not yet received by him. He proposed to bundle all the wires together, and could place 600 telephone wires in a space 5x2 inches.

Harry E. Dey, of 96 Grand street, announced that he had a system by which he could lay down 600 feet of conduit per day, without regard to the number of wires. No induction would be felt on account of the distance between the wires. No exhibit was made.

C. C. Gilman, No. 1 Broadway, N. Y., explained his drawings as representing a conduit 6x8½ feet, built of terra-cotta lumber, soaked in asphaltum, the walls to be 12 inches thick. This material can be tapped at any point. Its cost would vary from $65,000 to $105,000 per mile, according to size, and the branches about $5 per foot.

Ranald Macdonald is a believer in pine lumber. He proposed to embed the wires in well-seasoned pine boards, tongued, grooved and fitted closely, saturated in paraffine and coated with tar, then sheathed with copper, and encased outside with plank. He submitted a sample section.

J. J. C. Smith, from the Okonite Co., opened by announcing that physicians pronounced conduits unhealthy, and showed a sample of armored cable which may be buried just beneath the surface. The ends of the cables are brought to joint boxes at the street corners, inside which cross connections can be made with the side streets as required by the use of flexible conducting cords. One mile of cable containing 100 No. 16 wires may be put down for $10,000. Smaller cables are led from the joint boxes to the corner building, and thence along the block to each house.

The American Underground Electric Wire Co. submitted a model of a conduit, to be made of any suitable material. They recommend an artificial stone. This conduit may be from three to six feet in height. Brackets are provided on each side for telegraph and telephone wires, the electric light wires being placed below all, and protected by a sectional false bottom. The insulation furnished for wires is also included in this plan, which is called the Howe system. It was stated that insulation is so perfect that *inductive effects cannot be felt through it* when a telephone wire is wrapped spirally around 2200 feet of an arc lamp circuit.

The commission has engaged rooms at 23 West 23d street, where the sessions will be held hereafter.

A TELEPHONE DEAL LEADS TO MURDER.

The city of Lawrence, Mass., was the scene of an apparently deliberate murder on August 27, both parties being well-known citizens who had been intimately associated with each other in the telephone business. Henry K. Goodwin, at ten o'clock on the morning of that day, called upon Albert D. Swan at his office, where they engaged in conversation regarding previous business transactions. The bookkeeper in the adjoining room was soon after startled by the sound of a pistol shot, and turning quickly saw Mr. Swan reel and clutch the corner of his desk, with blood spurting from a wound in the back of his head. He fell to the floor and died in a few moments. Goodwin, who had deliberately shot him with a 32-calibre revolver, walked over to the telephone, notified the police that he had committed the deed, and offered to deliver himself up. He then walked to the station, where he stated that Swan had robbed him of all he possessed; that there was a period in a man's life when he could stand no more, and that he had reached that point. During the half hour's discussion he said Swan had laughed at him, and he was wrought up to such a state of desperation that he fired the fatal shot, and was ready to abide by the consequences.

Mr. Goodwin was one of the pioneers in the telephone business, which he embarked in as a member of the firm of Goodwin & Caldwell. Selling out to Swan and his partner, he went to Buenos Ayres in charge of the Bell telephone system there. Returning two years ago he entered the employ of the Molecular company. He is a native of Lawrence, where he has a family, and is about 38 years of age.

Albert D. Swan was a native of Tewksbury, Mass., where he was born in 1845. He was for many years in the insurance business, and subsequently became interested in telephone shares, thereby accumulating a fortune. It is said that he agreed to aid Goodwin financially in securing the patent for a switchboard, but neglected to pay the final fee. Meanwhile a patent was issued to Waite & Bartlett covering substantially the same ground. A joint arrangement was finally entered into to harmonize the conflicting interests, but Goodwin's friends assert that he might have made $40,000 out of the invention had it not been for Swan's carelessness.

Goodwin had just returned from a three weeks' trip in search of employment, but was unsuccessful. The defense is expected to be based on insanity.

STORAGE BATTERIES FOR A RAILWAY MOTOR.

An apparently successful test of the availability of an electric storage battery as a motive power for street passenger railways, took place recently upon the Union Passenger Railway from the

Digitized by Google

stables on Huntingdon avenue to Hampden, Baltimore county, Maryland. There were present upon the trial trip Messrs. A. G. Davis, A. B. Davis and A. B. Proal, representing the Viaduct M'f'g Co's establishment at the Relay Station, Baltimore and Ohio Railroad, a large portion of which was built for the manufacture of electric storage batteries, and the batteries used upon the above occasion were made by them; Mr. James R. Clarke, president of the company; Mr. A. H. Bauer, the electrician of the company, under whose direction the practical test was accomplished; Mr. W. W. Donaldson, assistant electrician; Mr. H. A. Foster, the electrician for the Daft Electric Company of New York, whose motor was used in connection with the storage battery; Mr. T. C. Robbins, superintendent of the railway company, who allowed the use of his motor, tracks and cars for the experiment. Eighteen persons were in the car, which, with the weight of the car, motor, &c., made a total of five and one-half tons. The car moved out of the yard, passing over grades of 235 feet to the mile and around curves with 75 feet radius with ease and comfort. The batteries used on the occasion were simply one-quarter h. p., not even made for motive power, but for incandescent lighting, but Mr. Bauer, the electrician, after figuring out the subject, decided that even with these small boxes a street car could be run, as was fully demonstrated. Forty-nine of the little one-quarter h. p. boxes were placed in the cab and connected with the Daft electric motor. On level grades only 20 of these boxes were used, the loaded car making easily six miles an hour. On the 235 feet grade the 49 boxes were used, equal to eight 6-10 h. p.

A storage battery especially constructed for street car purposes would consist of one h. p. boxes instead of one-quarter, and about 65 would be required. The storage company simply placed their small boxes in the motor car used by the Daft company. In practical usage these boxes will be put under the seats of the ordinary passenger car. The car will be started or stopped by simply turning a switch. An ordinary hand brake was used, though this work in future will be done by electricity.

"THE BEST LIGHTED CITY IN THE WORLD."

DETROIT STREETS.

Detroit has no street signs—that is, no signs with the names of the streets painted upon them. But Detroit has signs of streets. A rough, rotting, unrepaired pavement full of holes, such as jars and rattles the life out of a fine carriage to go over it faster than a walk, is a certain sign of a Detroit street. A lake of thin, slippery mud, caused by excessive sprinkling, sending up a continual steam of disease-breeding reek, spoiling the bottoms of ladies' dresses and covering the polished shoes of gentlemen with filth, is a sure sign of a Detroit street. A driveway, nearly half of which is obstructed by piles of brick and building material, and half of the rest by loading and unloading wagons, is another sign of a Detroit street. A passage for teams where everybody digs up the pavement at pleasure to fix a gas or water pipe and puts it down again so as to leave either a hillock or a hole, is another sign of a Detroit street. Utter darkness o' nights for two to four blocks, with nobody knows how many holes, piles of rubbish, or other obstructions there may be in the way, so that he has to depend solely upon the intelligence of his horse, is a very common sign of Detroit streets. And, finally, to meet with a lost stranger every two or three blocks, who stops one to inquire his way, is another continual sign of Detroit streets.—*Detroit Post*, Aug. 20.

ELECTRIC MOTORS IN MARYLAND.

The prudent and conservative city folks are anxious to have a substitute for horse and mule power on their street railways. The electric motors fill the bill exactly; but the timid Baltimoreans want them tried first on "some other fellow," and have generously and humanely selected country people as the other fellow. If the experiment succeeds it will be bravely adopted within Mayor Latrobe's jurisdiction. And if it proves disastrous to life or limb, "it will just serve the Belt people right for refusing to be annexed" to the joys and beauties of city taxation.

But the motor does seem to be a success—barring some shocking objections on the part of horses that have not yet learned all about the powerful ability of "the middle rail." Last Tuesday two of the motors ran for the first time on schedule all day from Huntingdon avenue stables to the terminus of the Union Line at Hampton village, making the round trip of four miles in 40 minutes without interruption or accident—the time being fully one-third less than by mule power. At each country road crossing a man is constantly on hand to prevent accidents to quadrupeds and to give warning to ignorant persons who may stray outside the city limits.—*Maryland Journal*, Aug. 22.

EFFECTS OF LIGHTNING IN CONNECTICUT.

The Norwich *Bulletin* gives the following account of the visitation of a thunderstorm August 25, which, it says, came down upon the city with a show of electricity and crash of thunder never experienced in that section. The lightning was almost continuous, and the successive thunder peals deafening. Wherever there were metal pipes or sinks the electricity seemed to play and snap and sizzle in a way that shocked the nerves of the timid. At one flash all the electric lights in the city were instantaneously extinguished, and the armature of one of the dynamos in the office of the electric light company was burned out and temporarily thrown out of use. Several stores using the electric light dismissed their clerks and closed their doors for the night. In the same shower the fire alarm telegraph system was thrown out of use, and several of the telephone circuits were burned out. There had been a steady rain all day.

THE DAFT MOTOR PLACED ON THE ELEVATED RAILWAY.

The electric motor "Benjamin Franklin" constructed by the Daft company has been placed on the track of the Ninth avenue elevated railway. The third line of rail which had been laid for some weeks, was found to have become quite rusty, therefore the first work of the motor was a trip over the route Wednesday night, with a grinding attachment in order to brighten the rails with which electrical connection is made. It was expected that everything would be in readiness for a public trial of the system on Monday, August 31, just after this issue has gone to press.

THE TELEPHONE CONVENTION AND RHODE ISLAND CLAM-BAKE.

The annual convention of telephone delegates will be held at Providence on September 8th. It is expected to be an unusually large meeting, followed closely as it is to be on September 11th, by the seventh annual gathering of electrical representatives of every description, without regard to age, sex, race, or previous condition of servitude, as the guests of Eugene L. Philips, on the romantic shore of Narragansett Bay.

ELECTRIC LIGHT AND POWER.

The Schuyler Electric Light Co. has secured the contract of lighting the streets of Richmond, Va., for five years, also the exclusive privilege of supplying light and power to private consumers, during the same period. Two hundred arc and 1,000 incandescent lamps will be required to begin operations. The city owns the gas works.

A corporation under the general laws of the state has been organized in Manchester, N. H., under the name of the "Forsaith Electrical Machine Co.," for the manufacture of dynamos, under the Whitney patent. The capital stock is $60,000 in shares of $100 each.

One of the largest single electric lights ever constructed was placed on exhibition at Seneca Falls, N. Y., on a recent Saturday evening. It is of 50,000 candle power, and is placed on the tower of a building at a height of 75 feet from the ground. It was intended to illuminate the whole village, but has not proved a success,

A company has been organized to establish, at Fenelon Falls, Ont., a power electric light plant, and by means of suitable wires serve the district within a radius of 30 miles.

The Electric Headlight Works, at Cuyahoga Falls, O., is about to ship ten outfits for use on the Northern Pacific Railway.

The Montezuma hotel, at Hot Springs, N. M., was destroyed by fire August 8th, the alarm being sounded at 11:30 P. M. By means of the electric gongs in each room, the 75 guests were immediately aroused and escaped. The building was lighted exclusively by the United States incandescent system. It was reported during the excitement that the building took fire from the wires, but there is no evidence that such was the case. The loss is placed at $300,000, insured for $250,000.

ELECTIONS AND APPOINTMENTS.

At the annual meeting of the Erie Telephone Co., recently held at Albany, N. Y., the following officers were chosen: James W. Bennett, president, Charles J. Glidden, secretary and treasurer, J. P. McKinstry, general superintendent, Charles A. Grant, transfer clerk.

MANUFACTURING AND TRADE NOTES.

Albert B. Herrick, manufacturer of electrical instruments in this city, assigned, August 17, to T. Frank Brownell. Liabilities about $3,500; assets, $1,500.

The Washburn & Moen Manufacturing Company, Worcester, has just finished the erection of a new foundry building, 100x 60, at Quinsigamond village, for the manufacture of steel for its own use.

PERSONAL MENTION.

Professor Robert H. Thurston has resigned from the faculty of the Stevens Institute of Technology, having accepted the position of Director of the Sibley School of Mechanical Engineering and of Mechanic Arts, recently organized in connection with Cornell University.

The most extreme point in Arctic exploration must have been reached by Sir William Thomson when he painted the north pole red.

THE TELEGRAPH.

Joseph Harris, who was arrested for alleged connection with the Detroit bank robbery in 1880, was released at Chicago July 30, on a writ of habeas corpus by Judge Anthony, who held that there were no grounds for his arrest except on a telegram, whereas an affidavit was necessary.

It was discovered at Conshohocken, Pa., July 30, that three unknown thieves had mounted the telegraph poles from West Conshohocken to Bala station, a distance of seven and a half miles, and had stripped and stolen two lines of copper telegraph wire of the Postal Telegraph Company. The total length of wire stolen is 15 miles, weight nearly a ton, and value $500. The thieves operated in broad daylight, passing along the road in a wagon, removing the wire and acting as if they were authorized employés.

Justice McCartney has filed a suit for $4,104 at Washington, D. C. against the Western Union Telegraph Co. Plaintiff was proposing to bid for the erection of a Government building at Terre Haute, Ind., and, on October 30, 1884, telegraphed A. B. Fitch there to know the price of brick and sand, that he (McCartney) might be guarded in making his proposal, notifying the company that, as the business was important, to hold the answer at the office, and he would call for it. He states that the answer was received the next day before one o'clock, but on calling for it he was informed that no answer had been received, that he made a similar inquiry a half hour later and learned the answer had been sent to his residence, and, driving thereto, found the telegram had been delivered. The bids were received at the Supervising Architect's office, at the Treasury, at two o'clock, and proceeding directly there, after obtaining the telegram, and putting in his bid, he was told that the time for receiving the bids had expired, and his proposal was refused. He states that his bid was for $200,600, and was the lowest, and would have been accepted if presented in time. He avers that by the carelessness of the company he has suffered loss as claimed.

THE TELEPHONE.

A telephone company may be held liable for an injury to a passer-by by the fall of its wires in a public street, caused by the weight of ice produced by water thrown over them by a city fire department while extinguishing a fire, according to the decision of the Supreme Court of Minnesota, in the case of Nichols vs. City of Minneapolis, decided on the 9th ult. Where such a company is given a license to string its wires over the public street, it is, in the opinion of the court, burdened with the duty of maintaining those wires in a safe condition, so that they may not become nuisances or endanger the safety of the traveling public.

The telephone subscribers in western Massachusetts, are said to be considerably irritated, because their yearly rentals have recently been increased. Many of them will doubtless discontinue.

The Lalande-Chaperon (oxide of copper) battery has been adopted for exchange and line service by the Société Générale des Téléphones of Paris.

In an action in the circuit court of Charleston, S. C., for $5,000 damages against a telephone company for cutting the telephone wire of a subscriber during the existence of a contract with the company, the jury found a verdict for the plaintiff for $1 and costs. The judge charged the jury that under the contract the plaintiff had no right to allow non-subscribers to use his telephone, but the company had no right to cut his wire until it had forbidden such a practice in writing. If the offense continued after such a notice the company had the right to cut the wire, but if not continued it had no right to do so upon a mere threat of the plaintiff that he would continue to violate the contract.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER *by* Pope & Edgecomb, *Solicitors of Patents for Electrical Inventions*, 11 Wall Street, *New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From July 7th to August 11th, 1885 (inclusive).

Alarms and Signals:—*Signal Apparatus*, M. W. and M. F. Parrish, 322,474, July 21. *Indicating Apparatus*, M. W. Grovesteen, 322,818. *Indicator for Bell Circuits*, W. A. Leipner and C. Brotherhood, 322,619. *Letter Box Alarm*, C. S. Ellis, 323,129, July 28. *Fire Alarm Box*, F. F. Loomis, 323,485, August 4. *Low-Water Alarm*, W. P. Ryman, 323,600. *Window Screen Alarm*, H. Garrett, 324,019, Aug. 11. *Annunciator*, C. E. Dey, 323,921.

Clocks:—*Alarm Clock*, C. Korfhage, 322,110, July 14. *Sparkless Circuit Breaker*, L. H. Spellier, 322,494, July 21.

Commutators:—*Switch*, E. Thompson, 321,462. July 7; F. Schaefer, 322,857, July 21; E. B. Nicolaus, 322,745; Leo Daft, 322,915, 322,916, July 28; H. K. Goodwin, 324,248, Aug. 11. *Spring Jack Switch*, J. C. Warner, 321,553, July 7. *Switch Board*, A. C. Mather, 323,182, July 28.

Conductors, Insulators, Supports and Systems:—*Underground Conduit*, J. Teggart, 321,865, July 7; W. D. B. Smith and F. J. Milliken, 322,018, July 14; D. H. Dorsett, 322,529, July 21; W. Walter, 323,241, July 28; W. B. Rogers, 323,964, Aug. 11. *Insulator*, E. T. Schoonmaker, 321,646, July 7. *Composition for Insulating Wires*, J. W. Ellis, 321,956, July 14. *System of Electric Distribution*. E. Thomson, 322,138, 322,139. *Conducting System*, John Kruesi, 322,385. *Tubular Cable*, P. Sorgue, 322,493, July 21. *Process of Making Kerite*, A. G. Day, 322,802, 322,803, 322,804, 322,805. *Rubber Compound*, L. S. Hoyt, 322,936, July 28. *Circuit Controller*, D. Rosseau, 322,973. *Insulator*, T. McGlory, 323,055. *Conductor*, R. A. Denison, 323,920. *Suspended Electrical Conveyor*, C. J. Van Depoele, 323,984, Aug. 11. *Cable Support*, E. M. Carhart, 324,225. *Method of Forming Screw Threads on Glass*, J. G. Pennycuick, 3.4,157. *Metal Tipped Cord*, W. H. Sawyer, 324,171.

Dynamo Machines and Motors:—*Dynamo*, E. J. Leads, 321,609, July 7; E. R. Whitney, 322,230, July 14; C. F. Ruset (deceased), 322,310; L. Bollmann, 323,108, July 28; E. Thomson, 323,975, Aug. 11; J. J. Bradley, 324,075. *Device to Prevent Sparking in Dynamo*, R. H. Mather, 321,990, July 14. *Support for Armatures of Dynamo*, same, 321,991. *Reciprocating Motor*, E. NEW YORK, OCTOBER, 1885.

THE STEARNS CONDENSER PATENT.

THE legal controversy which has been going on for some months between the Western Union and the Baltimore and Ohio Telegraph companies, has resulted in a victory for the latter, Judge Wallace having refused to grant the injunction asked for by the Western Union to restrain its rival from making use of the Stearns condenser in the operation of its duplex and quadruplex apparatus. Although it has attracted but little public attention, this case is in reality one of the most important ones in respect to the magnitude of the monetary interests involved, which has ever occupied the attention of the courts in the United States.

It was the application of the condenser by Joseph B. Stearns which first rendered it commercially practicable to operate long lines of telegraph, whether overland or submarine, by means of duplex telegraph apparatus. The United States patents for this invention were purchased by the Western Union Telegraph Company in 1873, and have unquestionably increased the value of its property to the extent of many millions of dollars. The patent was reissued in 1873, and again in 1882, the last reissue occurring about the time of the celebrated decision of the Supreme court in the case of *Miller* vs. *Bridgeport Brass Co.*, which laid down a radically new departure in respect to reissued patents. The ruling of the court in this case has since been followed with a strictness bordering on illiberality, and a considerable number of reissued patents which have come before the courts have been overthrown.

The counsel and experts of the Baltimore and Ohio company having advised it that in view of these decisions, the second reissue of the Stearns patent had in all probability rendered it invalid, under the present interpretation of the law, the bold move was made of applying the condenser to a large number of the main lines of the Baltimore and Ohio company, thus enabling it to quadruplex a large portion of its system and thereby enormously increase its carrying capacity. Suits were promptly instituted by the Western Union company and an application made for a preliminary injunction. Voluminous affidavits from nearly all the prominent experts in the country were filed on one side or the other, and some of the ablest counsel in the profession conducted the proceedings, among whom were Messrs. Dickerson, Duncan and Buckingham, for the Western Union, and Lowrey, Betts, Bacon and Hyde for the Baltimore and Ohio. The motion for injunction was heard before Judge Wallace, of the United States District Court, for the Southern District of New York, on September 2. Working models of the apparatus were set up in the court room, operated by the experts and explained to the judge by the counsel. The proceedings were of unusual interest, from a scientific as well as a legal point of view. The real point at issue was whether or not an attempt had been made, in reissuing the patent, to expand the claims so as to embrace a wider scope than those of the original patent.

Judge Wallace now decides that such is the case, or at least that the validity of the patent in its reissued form is not sufficiently free from doubt to justify him in granting a preliminary injunction. Had the injunction been granted, the consequences to the Baltimore and Ohio company would have been serious if not disastrous, as they would have been deprived of more than one-half of their telegraphic facilities terminating in New York city at a single blow.

The case will now proceed in the usual way to a final hearing on the merits, and the ultimate decision can hardly be reached under two or three years. There is little probability of any new evidence being forthcoming, not embodied in the affidavits already in the case, and hence there is no particular reason to anticipate a different decision even in the court of last resort. It is possible that the complainant may now reissue the patent once more, and restore it to its original form, abandoning the present proceeding and instituting a new one under the reissue, but in this event it could hardly hope to obtain a preliminary injunction, though it might have a better chance of success on final hearing than it now has.

This result is a substantial victory for the Baltimore and Ohio company, and very materially strengthens its position as a competitor of the Western Union company, for the general telegraphic business of the country. According to statements made in court, the profits of the Western Union have been disastrously affected by the competition which has only been rendered possible by the employment of this apparatus by its young and enterprising rival. If this is true, the outcome of the suit is a pretty serious matter for the Western Union.

THE INCANDESCENT LAMP TESTS AT PHILADELPHIA.

THE electrical exhibition held last year at Philadelphia, under the auspices of the Franklin Institute, was regarded as an especially important one by the electric lighting interests, largely in consequence of the extent and completeness of several of the exhibits of incandescent systems and apparatus. It was from the beginning the intention of the

Digitized by Google

management of the Institute to avail itself of the opportunity afforded by the exhibition to institute a series of comparative tests, the results of which should be beyond criticism, and which should at the same time afford to purchasers of electric lighting plants accurate and reliable information in respect to the characteristic excellencies and defects of the different systems. From various unavoidable causes not necessary to particularize, it was found to be quite impossible to properly examine and test several of the largest and most important exhibits during the time of the exhibition. Soon after its close, however, the board of management of the Institute, appreciating the disappointment that would be felt by all persons interested in electrical progress, not merely in this country, but throughout the civilized world, if such a favorable opportunity were allowed to pass without contributing anything of value to the scanty stock of trustworthy data existing in relation to the actual economy and efficiency of incandescent lamps, passed a resolution directing the president to take the necessary steps to complete, in a satisfactory manner, the examination of the exhibits, and authorizing the expenditure necessary to be incurred in making the tests. A committee, consisting of Lieut. J. B. Murdock, U. S. N., Ensign Louis Duncan, Ph. D., U. S. N., Prof. W. D. Marks, of the University of Pennsylvania, and Geo. M. Ward, M. D., photometric expert of the Philadelphia gas works, were accordingly appointed to conduct examinations and tests of the efficiency and life of incandescent lamps.

The report of this committee, whose labors were continued for several months, has been awaited in electrical circles, with much interest, and has recently made its appearance. The report is quite voluminous and is somewhat too detailed for reproduction entire in the columns of this journal, but we have given elsewhere a sufficiently full abstract of its contents and of the results arrived at, to enable our readers to understand the valuable and important character of the work. We believe we do not err in expressing the opinion that the report of the committee is more exhaustive and complete than anything which has yet appeared in any part of the world in relation to the subject under discussion. The results of the tests of the life of lamps are of especial value from a commercial point of view; but many will share with us in the regret that through an unfortunate complication of circumstances, the tamadine lamps entered by Mr. Weston, although found during the preliminary trials to be defective were nevertheless under the rules subjected to a competitive test, in spite of his protest. We have no disposition to censure the members of the committee for their action in this matter, and indeed, it would seem that a strict compliance with the code of regulations by which the competitors had agreed in advance to abide, left the committee no alternative, when Mr. Edison's representative finally insisted that the tests should be proceeded with under the code. While it was clearly within his right to do this, and the incentive was particularly strong from a business point of view, still his action cannot but be regretted from a scientific standpoint, as it precluded the possibility of a satisfactory comparison between the two lamps, which are thus far the leading competitors in the United States. The results of such a comparison would obviously have been of greater actual value than any other point determined by the committee, but as it is, we are still without definite knowledge of the relative efficiency and economy of the lamps which are at the present time being put upon the market by the Edison and the United States electric lighting companies.

We have only space to call attention to a few of the many interesting facts disclosed by the tabulated results given in the report. The high efficiency claimed for the Woodhouse & Rawson (English) lamps, in tests reported from abroad, appears to be partially confirmed by the Philadelphia tests, which give for these lamps a mean efficiency of 204.9 spherical candles per electric horse power, being exceeded only by the Stanley-Thompson lamps which reached the high figure of 216.1 candles. The Edison lamps, while giving a comparatively low figure for efficiency, the mean being 169.2, surpassed all the others in length of life. A remarkable circumstance which is especially noticeable in the life tests, is the gradual falling off in efficiency, as shown by the diminution of the candle power, the Edison lamps declining fully one-half during the test of 1,000 hours, and many of the others in about the same proportion. In this respect the Weston 70 volt lamp made a comparatively good showing, as the tables indicate. From a practical point of view, the life of an incandescent lamp must be considered to be determined by the rapidity of this fall of efficiency, as it is of course necessary for the consumer to replace any lamp whose illuminating qualities have sensibly diminished, by a new one, without waiting for its actual extinction.

There is much in this report which merits careful study; and we have no doubt that the points we have suggested will receive due attention from our electricians.

The committee deserve high praise for the thoroughness, patience and evident impartiality with which they have performed their wearisome and somewhat thankless task, but we can assure them in behalf of the profession, that the value of their work is far from being unappreciated, and that its importance will come to be recognized more and more, as it receives careful criticism and consideration.

THE GOVERNMENT AND THE TELEPHONE PATENTS.

The announcement that a suit had been instituted by the law officers of the United States government, in the federal court at Memphis, to annul or set aside the Bell patent, has created a mild excitement in telephonic circles. The facts in the case appear to be substantially as follows: In October, 1883, an organization calling itself by the peculiar title of the Pan-Electric Telephone Company, was formed in Memphis, Tenn., with a capital of five million dollars, to exploit the inventions of one J. Harris Rogers. Four more or less prominent Tennessee politicians were associated with Rogers as incorporators, one of whom, Hon. A. H. Garland, afterwards became Attorney-General of the United States, and as it appears is still the owner of one-fifth of the capital stock. Several of the other incorporators also hold important offices under the present national administration. In July last, the American Bell Telephone Company made application to the United States circuit court, in the district of Maryland, for a preliminary injunction against the Pan-Electric and its local companies

Digitized by Google

doing business in that state, and an order was issued to the defendants to appear on September 15, and show cause why a preliminary injunction should not be issued.

On August 29, certain parties in the interest of the Pan-Electric company petitioned U. S. District Attorney McCorey, of the western district of Tennessee, setting forth at great length that the Bell patents had been originally obtained by fraud in the patent office, and requesting him to report the matter to the department of justice, to the end that leave might be granted to him, in his official capacity, to institute suit against the owners of the Bell patents. The papers having been laid before Attorney-General Garland, leave was duly granted Mr. McCorey to institute proceedings in the name of the United States, and J. R. Beckwith, George Gantt, Casey Young and General Wright, all persons interested in the Pan-Electric and other rival telephone enterprises, were appointed special government counsel.

When the Pan-Electric injunction case came to be heard in Baltimore on September 15, before Justice Bond, the defendants' counsel endeavored to have the proceedings suspended to await the issue of the suit of the Attorney-General, but with only partial success. The court granted an order postponing the hearing until November 2, but meantime restraining the defendants from extending their business in any manner.

The bill filed by the Attorney-General contains all the familiar allegations which have been unsuccessfully put forth in prior suits, as to the anticipating inventions of Reis and others. The only new allegation is that of a fraudulent issue of the Bell patent, by the patent office.

It is very generally known that a caveat containing a full description of the electric speaking telephone was filed by Elisha Gray on the same day with Bell's application for a patent. The bill alleges that the contents of this caveat were wrongfully communicated to Bell by an official in the patent office, and that in view of the knowledge thus obtained, Bell subsequently amended his application, so as to claim the invention of Gray, which invention was not specified, claimed or described in his (Bell's) original application.

We do not know what proof the complainant may have, in respect to the malfeasance of the officials in the patent office, but the records show conclusively that the fifth claim of the Bell patent, the one which has been repeatedly sustained by the courts, was never amended, modified or changed in any way, from the time when it was sworn to by Bell, more than three weeks before the application was filed, until it was issued in the form in which it stands to-day, except by the insertion of the wholly immaterial words, "substantially as set forth." Even if it were true that Bell obtained a knowledge of the contents of Gray's caveat, he nevertheless did not alter or amend his application in consequence of this knowledge. Hence it would seem, that even were the fact of the unlawful disclosure of the caveat proven, the effect would be, not to annul the Bell patent, but at the furthest, to reinstate Gray's caveat, and institute regular interference proceedings in the patent office, so that Gray, in case he established his priority of invention by the necessary proof, might have a patent also, and thus be placed on an equal footing with Bell before the courts and the public.

It is hardly necessary to say that even the United States government has no power to annul or set aside a patent, except for good cause. We do not see that so far as disclosed, this action has anything material to support it, which has not already been passed upon by the courts, except the single allegation of the fraudulent amendment of the patent application, which an inspection of the records shows to be false. On the other hand, the personal interests of the Attorney-General are so clearly of a character to profit by the successful issue of such a suit, that an immediate and complete explanation would seem to be necessary to avoid a grave political scandal.

SUBTERRANEAN WORK IN BROOKLYN.

The electrical companies of New York city, who are looking to the investigations of the subway commissions, to devise plans by which they are expected to comply with the law, will find little information in the report of the Brooklyn commission. It is in the main confirmatory of the opinions of most practical men, whose experience had led them to believe that the original underground law was inoperative as well as unjust.

It takes the ground that it is not primarily the duty of the board to solve electrical problems for the benefit of the electrical companies, and that it is concerned in such questions only so far as they affect repairs or changes in the wires, which will involve the disturbance of the streets. Such being the admitted functions of the commission, its approval of the proposed plan as is described in the report is apparently open to criticism. No provision appears to have been made for electric light wires, and the structure itself can scarcely be considered of a permanent character. Modern public works embrace neither the pump-log aqueducts, nor the wooden sewers of past generations, and it is extremely doubtful if wooden pavements would meet with popular approval in some of our neighboring cities. The fact that the lumber is creosoted, while perhaps preserving the wood from decay, does not prevent the ingress of sand, water, sewer or illuminating gas, none of which should be admitted into what would be considered a perfect conduit. If the commission has no further power it should certainly prohibit temporary underground work, and if nothing better can be discovered than such an apology for a subway as is described it would be wise to permit the wires to be strung overhead for some time to come.

The time was rapidly approaching when the companies must have entered voluntary upon this work. Although a date was arbitrarily fixed for the enforcement of the law, it would have been far preferable to have extended the time than to permit the inauguration of a series of experiments which will involve not only the occasional digging up of the streets, but the eventual reconstruction of the entire system. Such a contingency should be avoided in this city. If a system cannot be secured that is permanent beyond question, affording facilities for electrical wires of every description, then its introduction should be deferred, rather than permit the annoyance which must arise from continual repairs, improvements and eventual abandonment of an untried invention.

ARTICLES.

THE EFFICIENCY AND DURATION OF INCANDESCENT LAMPS.

THE special committee appointed by the Franklin Institute to conduct the tests of the incandescent lamps at the Electrical Exhibition has published a very complete report of its work from which the following extracts and tables are selected:

The scheme for a duration or life test of incandescent lamps was organized during the electrical exhibition by the executive committee. It had been recognized that tests of incandescent lamps for the determination of the efficiency alone afforded no data for deciding upon their relative value, the lifetime of the lamp being an important factor in the question of economy. A test which should furnish information on this point would be very valuable. Plans were early made for such a test, but as the time required was such that it could not be conducted by the photometric group of the board of examiners, it was placed in charge of a special committee, and invitations were extended to the principal incandescent light companies to enter their lamps. Before the necessary arrangements could be completed several of the members of the special committee were compelled by their engagements to leave Philadelphia.

The board of managers of the Franklin Institute thereupon placed the conduct of the tests in the hands of its president, who filled the vacancies existing in the committee, and authorized preparations for conducting the test on a larger scale than was possible during the continuance of the Electrical Exhibition. Three rooms in the exhibition building were set apart for the test.

A code had been prepared, specifying how the test should be conducted. This code was signed in December by Mr. Weston and Mr. Upton, representing the interests of the United States and the Edison companies. The Brush-Swan and the Bernstein companies declined to enter their lamps. The Franklin Institute entered a lot of Woodhouse and Rawson lamps, obtained from the Van de Poele Company, and also two grades of the Stanley-Thompson lamp, made by the Union Switch and Signal Company, of Pittsburg. The president of the Franklin Institute subsequently entered, for efficiency measurements, and for such a test of duration as circumstances would permit, a lot of Weston lamps (paper carbon), furnished by Mr. Weston; a lot of Woodhouse and Rawson lamps, received from the Edison Lamp Company, and a lot of White lamps, from the Electrical Supply Company.

In order to secure satisfactory results, and prevent needless discussion, the following code was agreed upon for the conduct of the test:

Proposed Code for Duration Test of Incandescent Lamps to be made by the FRANKLIN INSTITUTE *of the State of Pennsylvania.*

The parties hereto subscribing do agree to accept the services of the examiners herein named, and to abide by the method adopted for the test, and by the results obtained, without appeal.

NAMES OF EXAMINERS.

Lieut. J. B. MURDOCK, U. S. N.	Ensign L. DUNCAN, U. S. N.
Prof. WM. D. MARKS.	Dr. G. M. WARD.

Each company to enter twenty lamps. The examiners will select fifty lamps from a supply furnished by the companies, of not less than one hundred lamps. Twenty of these will be used in the preliminary adjustment of the circuit and then replaced at the beginning of the test by twenty similar ones, until then unused, save for preliminary determinations.

A preliminary test of each lamp under normal conditions will be made before the beginning of the continuous test, and the time used will be credited to each lamp.

This preliminary test will determine the spherical intensity of the illumination and the reduction factor.

The Franklin Institute shall have the right to enter lamps of different kinds for the test, such lamps to be treated in all respects as though entered by a competing company.

The difference of potential between the mains will be kept at 120 commercial volts. Weston's incandescent automatic regulator will be used, and no other adjustment of the potential of the mains will be attempted, save in the case of wide variation. A volt meter will be kept in circuit all the time.

A resistance of german-silver wire will be placed in circuit with each lamp, and a preliminary adjustment made, to give the lamp its proper difference of potential.

Exhibitors will give the potential required by their lamps. Unless the lamps are separately marked, all lamps of the exhibitor will be considered as exactly similar.

An Edison "T" dynamo, driven by a Porter-Allen engine, will be used. The circuit will be opened occasionally and the lamps allowed to cool.

Lamps shall be considered as out of the test when they fail to burn, whether due to breaking of glass or filament. When a lamp gives out it will be replaced by one requiring substantially the same difference of potential. The first three lamps of each company which are broken shall be replaced by others for which the preliminary measurements have been made, to be used only in case of accidental breakage.

The test may be declared ended at any time when in the opinion of the committee one system is so far in advance that a longer test could not change the result.

MEASUREMENTS.

Measurements of currents, difference of potential between terminals of lamp, and photometric intensity, will be made. The lamps will be arranged in a circle, having the photometer bar for a radius, and will be placed with the plane of the loop perpendicular to the bar. All measurements will be reduced to mean spherical intensity, by multiplying the intensity measured, by a reduction factor determined for each lamp. Photometric measurements will be made as necessary, but not oftener than once daily.

Electric measurements will be made daily.

A record will be kept of each lamp, in which all data relating to it will be entered.

Weekly reports will be made to the Franklin Institute, of the observations made, and showing how long each lamp has been under test.

METHODS.

The legal ohm will be considered the standard of resistance. The ampère will be determined by the silver voltameter, and checked by calculation of the constant of the current galvanometer used. The volt will be taken as that E. M. F. which produces a current of one ampère in a resistance of one legal ohm. The ampère equivalent of silver as determined by Lord Rayleigh will be accepted as correct.

Currents will be measured by a tangent galvanometer, the constant of which will be determined by the silver voltameter, and checked by calculation.

A standard resistance of german-silver wire wound on a reel will be carefully measured in turpentine or neutral oil, the temperature being observed. The potential galvanometer may be calibrated by connecting to the terminals of this resistance while a current simultaneously measured is passing through it. The temperature of the liquid will be observed and the resistance corrected therefor.

Calibrations will be made frequently during the test.

Potential may be measured by a mirror galvanometer in a shunt circuit of high resistance.

Each company will be permitted to have one authorized representative in attendance throughout the test, and every facility will be given to those representatives to inspect the working of the test that will not interfere with its progress.

The Franklin Institute agrees to keep the lamps under proper surveillance, and to take necessary precautions for their safety. Lamps accidentally broken will not be charged against the companies.

The right is reserved to discontinue the test at such times and for such periods as may seem advisable or necessary.

A preliminary test will be made before the actual test begins, to insure good working.

In case any objection be made, or difference of opinion should arise between the committee and the contestants, the unanimous vote of the committee shall be final.

If, however, there be not a unanimous vote, the minority of the committee shall appoint one referee and the majority another; these two shall appoint a third referee.

The decision of a majority of these referees shall be final.

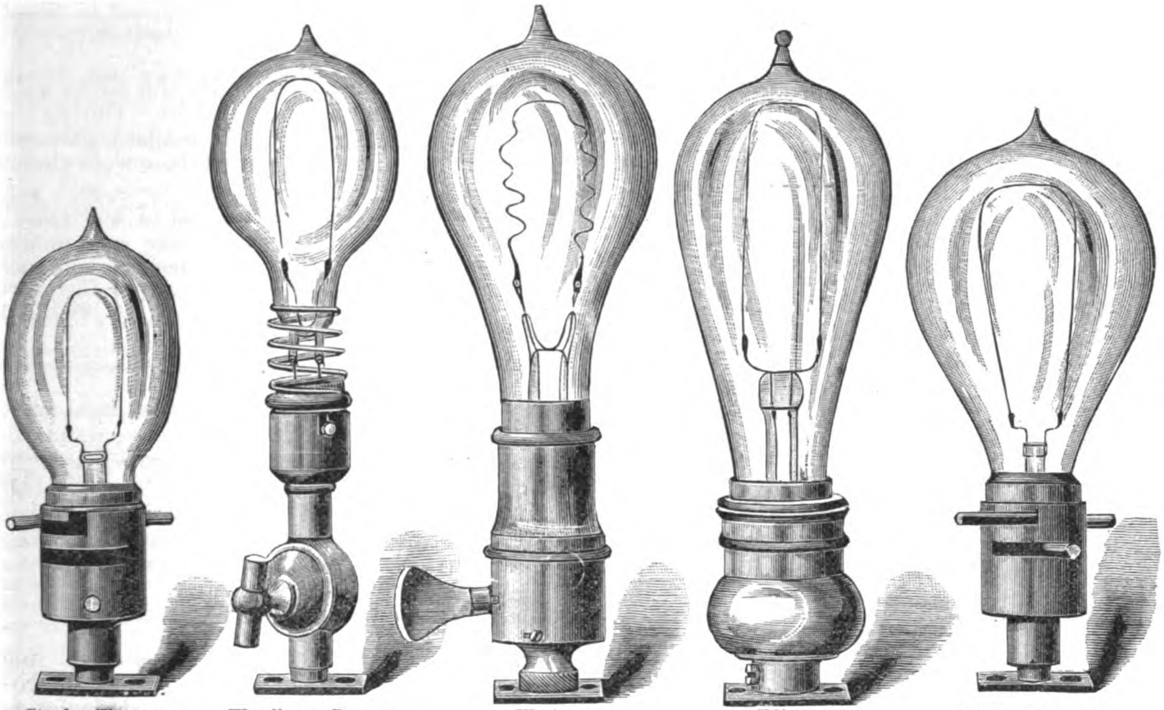
(Signed) FRANCIS R. UPTON.
United States Electric Lighting Company,
per EDWARD WESTON, *Electrician.*

The test began with the following lamps entered:

20 Weston,	110½	volts.	Tamadine carbon.
20 Edison,	94–100	"	
10 Woodhouse & Rawson,	55	"	
10 Stanley-Thompson,	96	"	
10 " "	44	"	

Digitized by Google

The latter lamps were requested to be entered at 16 c.p. The committee, after a preliminary trial of several of the lamps, fixed on the potentials of 96 and 44 volts, respectively, for the two grades, as approximately representing



Stanley-Thompson. (44 volt.) Woodhouse-Rawson. Weston. Edison. Stanley-Thompson. (96 volts.)

that candle power, and the lamps were entered at these potentials.

No official information was furnished the committee as to the process of manufacture of any of the lamps. Their general appearance and the relative size is shown in the cut.

PHOTOMETRIC MEASUREMENTS.

The measurements of the spherical illuminating power of the lamps were made with the object of obtaining the average candle power of the lamps, and to avoid the doubt as to the total amount of light which might arise from the various forms of carbon (many of them distorted in manufacture) used by different makers.

Sixty-five measurements or more were made on each lamp. The method pursued may be the more easily understood by a comparison with the parallels and meridians of the earth; referring to points by their latitude and longitude.

The lamp was placed in a vertical position, with the plane of the shanks of the carbon at right angles to the photometer bar. The side nearest the bar was marked for future reference. The top and bottom of the lamp were assumed as the north and south poles respectively, and the vertical circle at right angles to the plane of the shanks of the carbon as the prime meridian. The lamp, after adjustment as above, was first rotated horizontally, and 13 measurements were made in the equator at equal angles of 30 degrees, the last checking on the first. The mean of these measurements gave the "mean horizontal intensity."

Starting again from the first position, the lamp was rotated in the plane of the prime meridian and 13 measurements were made at equal intervals of 30 degrees, the last checking the first, and making four measurements of the point 0° latitude, 0° longitude. The mean of these four was called the "standard reading." If any noticeable discrepancy was noticed, the measurements at this point were repeated. As this point was that on which the calculations for the duration test were based, its careful determination was essential.

The lamp was then moved 45° horizontally, so that 0° latitude, 45° longitude E. was towards the photometer. It was then rotated in the vertical plane passing through that point and 13 measurements made as before, at intervals of 30 degrees, the last checking the first.

The lamp was next moved 45° horizontally, so that 0° latitude, and 90° longitude E. was towards the photometer, and 13 measurements made in that meridian as before.

Lastly, the lamp was rotated till 0° latitude, 135° longitude E. was towards the photometer and 12, 30 degree measurements made in that meridian, checking with a 13th.

This makes a total of 65 measurements on each lamp. As the sockets in use with all the lamps prevented the exit of any light from the bottom or south pole of the lamp, the reading at that point was always taken as zero.

The measurements were combined as follows:

The mean of four readings at the north pole of lamp...	1
Four measurements on each of the parallels of 60° N. and 60° S. on the prime meridian and 90° meridian circle	8
Eight measurements on each of the parallels of 30° N. and 30° S. at the intersection of the meridian circles of 0°, 45°, 90° and 135°	16
Twelve measurements, 30° apart, on the equator	12
One zero reading for south pole (base of lamp)	1
Making a total of	38

By laying down the points on a sphere it will be found that they are very nearly equidistant, being somewhat nearer at the equator than at the poles.

The average of the illuminating power at these 38 points is taken at the mean spherical intensity of illuminating power.

Figure 1 shows the location of the 38 points. It is a photograph of a Mueller lamp of nearly spherical shape, around which four rubber bands are stretched to show the four meridian circles, and one rubber band to represent the equator. The square black patches show the 38 points.

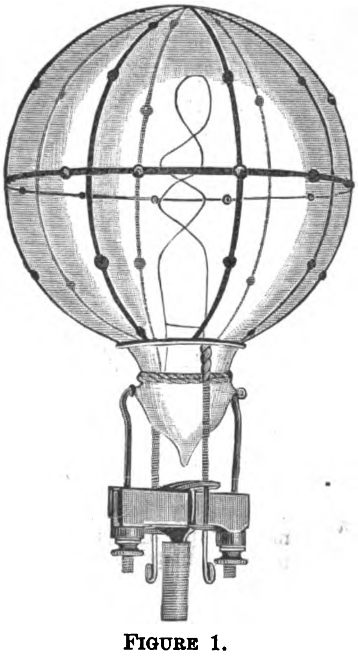


FIGURE 1.

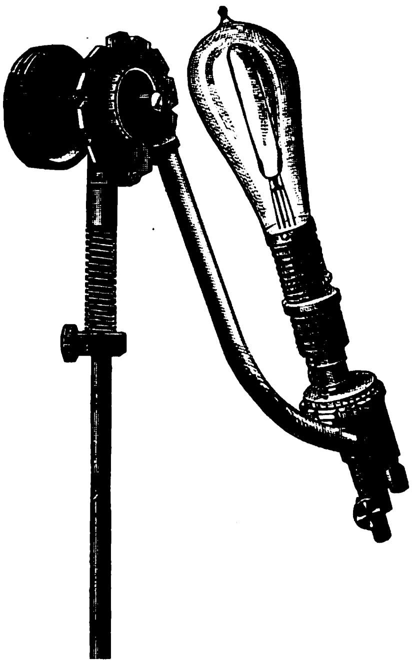
The particular lamp to be tested being placed in the lamp-holder, the potential was adjusted by means of the resistances in circuit with the lamp, and the candle power, current and potential determined. The current reached the lamp through wires dipping into mercury cups in the

piece of wood at the bottom of the lamp compartment. If a change occurred in the potential, photometric work was stopped until the potential was adjusted. Observations of current were taken about every four minutes.

The "reduction factor" used during the test for duration, was obtained by dividing the mean spherical intensity of illumination by the "standard reading" or the mean of the four observations at 0° lat., 0° long.

ELECTRICAL MEASUREMENTS.

The electrical measurements were made in a small room especially prepared for the purpose. The potential of the lamps was measured by a Wiedemann mirror galvanometer in a circuit of high resistance. The instrument employed was made by Hartmann, and was chosen on account of good damping. It had a Siemens bell magnet, suspended in a cylindrical cavity in a solid copper block. The mirror was attached to the suspending rod of the magnet. The fibre was about 15 centimetres in length, and was without appreciable torsion within the deflections used. The deflection of the magnet was observed by a telescope and scale at a distance of 176 centimetres, afterwards increased to 180. The galvanometer resistance was about two ohms, two coils, one on each side of the magnet being used in series; but a resistance of either 50,000 or 100,000 ohms was used in circuit with the instrument, the former being employed with lamps of less than 60 volts potential, the latter with others. The galvanometer was loaned to the committee by Prof. H. D. Todd, of the U. S. Naval Academy, and the reading telescope by Messrs. Jas. W. Queen & Co., of Philadelphia, who (through Mr. Walton, the head of the Philosophical Department) extended to the committee throughout the test, every convenience that their large stock of physical apparatus afforded.



Revolving Lamp Holder.

During the preliminary measurements for efficiency the potential was regulated by an observer at the telescope, who watched the deflection and recorded the potential at regular intervals, signaling any change to the photometer room, where the potential was adjusted by a change of resistance in the lamp circuit. In general this method worked well, but occasionally, through irregularity of the engine, the potential would fluctuate. Whenever the working conditions were bad, the results were rejected and the measurements repeated.

The lamp currents were measured by a tangent galvanometer, specially constructed for the test by Jas. W. Queen & Co. It consisted of a single coil of six turns No. 8 wire, on a brass frame of 60 cm. diameter. The base was of wood, two feet wide, resting on leveling screws. Both galvanometers stood on large wooden posts, buried two and a half feet in the earth, and out of contact with the floors or walls of the building. The needle and compass were loaned for the test by Mr. Weston. The circle was divided to 10′ and could be read by a magnifying glass to 1′ of arc. The maker's adjustments of the needle in the centre of the galvanometer coil were carefully verified.

The code prescribed the method by which the electrical units should be reproduced, and was strictly adhered to.

CURRENT.

The ampère was determined both by the silver voltameter and by calculations of the constant. During the test 38 calibrations were made of the tangent galvanometer by the silver voltameter. Eight of these were purely experimental, to determine the best conditions, and several of the others were rejected on account of bad conditions. All those were accepted in which the current was steady, the deposit good, and the time accurately determined. The current was supplied at first by a gravity battery, in multiple series, but later by a secondary battery.

RESISTANCE.

The ohm was by the code to be the Paris or legal ohm. In reproducing it, the committee had access to the standards and apparatus of the Johns Hopkins University, used by Prof. Rowland in his recent determination. The standard resistances of the test and the Wheatstone bridge used had their values carefully determined in Baltimore.

In the reductions the legal ohm was taken as 1.0112 B. A. units.

ELECTROMOTIVE FORCE.

The volt was determined by the fall of potential in a given resistance due to a known current. A reel of No. 22 german-silver wire was made by winding the wire on fine glass rods which were let at each end into pieces of black walnut. The turns of the wire were kept apart by turns of silk cord around the posts. The axis of the reel was surrounded by a stirrer, by which the excessive heating of the wire while in the bath was prevented. This reel was immersed in turpentine and later in refined petroleum (300° fire test, furnished by the courtesy of the Standard Oil Co.), and while in use in calibrations the liquid was kept in motion by the stirrer and the temperature regularly recorded. The ends of the wire were taken to double binding posts at the top of the reel, to which the current and potential leads were connected.

MEASUREMENTS OF EFFICIENCY.

The general method of making the observations for efficiency has already been stated. The committee aimed to test each lamp at its normal potential as stated by the makers, and to place it in the test for duration at the same potential, that the relation between efficiency and life might be traced. A few lamps were tested at two or more potentials. The efficiency measurements were begun at the earliest moment when it was thought that the arrangements for the test were sufficiently advanced to secure good results.

AN EXPLANATORY CORRESPONDENCE.

In submitting its report on the tests of the Weston 110½ volt lamps, the committee deemed it proper to insert the correspondence which had taken place with Mr. Weston, and Mr. Edison's representative.

The 110½ volt lamps were received from the United States company in January. Efficiency measurements were made on the 5th, 6th and 7th of February. On the 18th of February, Mr. Weston visited the exhibition building, was shown the results of the efficiency measurements on his lamps, examined into the installation, and the working methods of the test, and thinking the candle power of some of them low, addressed the following to the committee :

PHILADELPHIA, February 18, 1885.

Having examined the methods of testing used and the results obtained in the efficiency determinations, I would request a re-measurement of my lamps numbered 4, 6, 15 and 17.

I am satisfied that the methods used are such as will produce correct results.

EDWARD WESTON.

The lamps designated were re-tested and the accuracy of the former measurements verified. On the 7th of March the preliminary run for working methods began. Owing to irregular working of the engine, causing flickering in the lamps, it was prolonged a week, that better working might be secured. On March 17th the committee had arranged to begin the duration test at 2 P. M. Very shortly before that time, the representative of the United States company, who had not been in attendance on the

tests for several weeks, although his presence had frequently been solicited, arrived with the following letter from Mr. Weston:

LABORATORY OF EDWARD WESTON, 107 ORANGE STREET, NEWARK, N. J., March 16, 1885.

Prof. WM. D. MARKS.

DEAR SIR:—The very marked difference in candle power of our lamps, as shown in the tabulated results of the tests made in Philadelphia, surprised me very much, particularly as our lamps are remarkably uniform in this respect, and must necessarily be so when properly made, owing to the peculiar method of treating the loops.

After arriving here I commenced to investigate the matter, and soon found that you had been supplied with a singularly bad lot of lamps; the defect being due to imperfect baking of the loops. This has been so imperfectly done that you will find it impossible to maintain the candle power uniform for even a very short period of time without increasing the E. M. F. The resistance of the loops will rise rapidly, and the lamps will rapidly deteriorate and fail in such a short time as to leave no doubt in your mind that if we made such lamps regularly we could not possibly continue to do business. In other words, the lamps are thoroughly worthless.

In view of these facts, I think it is useless to spend any time on the lamps of our make which you now have, and since there is no provision in the code for such a contingency as has arisen, I respectfully submit this statement of facts to the committee, and ask for a careful consideration of the matter.

Deeply regretting that anything should have occurred on our part to still further prolong and increase the cost of a series of tests which must necessarily be very tedious and expensive, I remain, Yours respectfully, EDWARD WESTON.

The members of the committee present agreed with Mr. Weston that the code provided no remedy for a case of this kind, and agreed to postpone the beginning of the test and to refer the matter to the Edison company, that the competing parties might enter upon new arrangements. The Edison company, through Mr. Upton, agreed that Mr. Weston should have the privilege of entering another lot of lamps of the same general character and grade as those already tested, and the committee, desirous of obtaining good lamps for test, agreed to measure them when received. On the 1st of April a conference took place between Messrs. Weston and Upton, the president of the Franklin Institute and a portion of the committee, at which Mr. Weston stated he thought there would be no doubt but that the new lot of lamps would be on hand within a week.

The allotted time having expired without anything being received from him, Prof. Marks notified Mr. Weston that the engagements of some of the members of the committee compelled the fixing of April 11th as the date beyond which further postponement was impossible.

On April 9th another conference was held, at which the representative of the Edison company objected to Mr. Weston withdrawing his lamps, and addressed the following letter to the committee:

Prof. WM. D. MARKS, *Chairman.*

DEAR SIR:—The Edison company desire that the test of lamps be proceeded with under the code without further delay.

Respectfully,
FRANCIS R. UPTON.

65 Fifth avenue, April 9th, 1885.

This request that the test should be continued under the code, the failure of Mr. Weston to provide new lamps, together with the impossibility of further delay if the test was to take place at all, gave the committee no option but to proceed under the code with the lamps on hand. In order to prevent any misunderstanding on the part of Mr. Weston, he was notified by letter and telegram that the test would begin on the 11th. A few hours after the beginning of the test, the following telegram was received:

Prof. WM. D. MARKS.

Your telegram surprised me. The lamps have been withdrawn. Our position in this respect is fully caused by your letter of April 8th. I presumed that this was the final judgment of the committee pending a reply from me. There is no clause in the code by which the Edison company can compel the committee to proceed as indicated in your telegram; neither the committee nor the Edison company have any right to re-enter our lamps without our consent. My letter in reply to yours of the 8th will fully cover these points. EDWARD WESTON.

The matter was immediately considered by the full committee, and answered as follows:

PHILADELPHIA, April 11, 1885.

EDWARD WESTON,
Newark, New Jersey.

In reply to your telegram of to-day, the committee have considered the question you raise. It was understood by them that the verbal conference of Thursday evening, at which you were present, made it clear that the formal demand of one of the competitors that the test should proceed left the members of the committee then present no option in the matter, and rendered the letter of the 8th nugatory. Under the provisions of the code any questions between the contestants and the committee can be settled by a unanimous vote of the committee, and the undersigned give their decision that under the code no withdrawal is possible, and their letter of the 8th becomes invalid when questioned by a contestant.

J. B. MURDOCK, G. M. WARD,
L. DUNCAN, WM. D. MARKS.

Subsequently another letter was received from Mr. Weston and another conference held at his request, but the committee regarded their action as final and nothing was done.

The committee present the above as a matter of justice to Mr. Weston, and also as an explanation of their own course of action.

ATMOSPHERIC ELECTRICITY.

BY P. H. VAN DER WEYDE, M. D.

(President of the N. Y. Electrical Society.)

IN the August number of the ELECTRICIAN AND ELECTRICAL ENGINEER, Prof. Blake publishes a reply to my remarks upon his paper under the above heading, which reply requires a notice from my side. It was at the request of several members of the New York Electrical Society (before which, in the absence of its author, the paper was read by Dr. Keith) that my remarks were published at the same time. For this purpose I wrote them down, shortly after the meeting. While doing this, I found that I could have said a great deal more to elucidate the theory which I have been teaching since 1840, and to which the later labors of Riess, Wiedeman, Piazzi, Thomson and others, have only added details and corrections, without upsetting its fundamental principle, which is also accepted by Professor Blake, namely, the theory first announced by Peltier, 50 years ago,[1] and soon adopted by Quetelet, of Brussels, and Lamont, of Munich, that *the earth's surface possesses naturally a negative charge of electricity.* As, however, my remarks appeared to occupy almost as much space as the paper to which they were appended, I refrained from adding anything more. I am glad that Prof. Blake's reply gives me an opportunity to fill up omissions incident to extempore speaking.

When, under the comprehensive title of "Atmospheric Electricity," a writer begins with mentioning opinions of the Greeks and Romans in regard to the nature of thunder storms, and refers to experiments of Franklin, Becquerel, De la Rive, and others, one would naturally expect that some attempt would be made to show in how far the theory which the writer adopts will explain the source of atmospheric electricity. No wonder that a feeling of disappointment was produced when I became aware that the contents of the paper were confined to the account of a few experiments by which the writer failed to transmit electricity, either by convection or by conduction, what others claim to have accomplished. As in years gone by I had also made experiments of the same kind, studied the causes of frequent failures, and believed to have found them, I could not refrain from speaking; and after seeing that no member of the society offered any remarks, I gave an account of the convictions I had arrived

1. Garnier: Meteorologie. Brussels, 1837; p. 221.

Digitized by Google

at more than 20 years ago, namely, *the influence of the dew point*, the importance of which upon the subject under discussion Prof. Blake, to my regret, "fails to grasp;" at least, in his reply he does not make the slightest allusion to it. Perhaps he considers it an insignificant suggestion, but I think it worthy of serious consideration, as it is one of the causes of the discrepancies in the results of various experiments. I hope presently to show that most likely it is *this*, and not the greater delicacy of modern appliances, which is at the bottom of the question.

If the title and introduction of the paper had conformed with its contents, I would certainly not have charged the writer with onesidedness, but as he starts with the theory of Peltier, referred to, I expected, in connection with the title, a less onesided consideration of this beautiful proposition, so fruitful in the deductions which may be drawn from it. The suggestion which he makes, that I perhaps expected that the paper would "discuss all the theories as to the cause of atmospheric electricity advanced in times past and present," is simply absurd, because there are few subjects on which so much has been written; in fact, not to speak of what may be found in text books and cyclopedias, the number of separate papers on the subject in English, French, German, Italian and Dutch, is truly appalling, and constitute a library by themselves; while the diversity of assumptions and opinions is so great that physicists are in this respect on an equal footing with theologians and lawyers, being also able to prove their favorite notions, whatever they may be, by quotations from supposed authorities, who, as I hope to show, are not infallible. As an instance, I will here merely make the preliminary remark, that most of them overlook the fact that the terrestrial surface is very rough, and not at all like a smooth brass plate, "heated by a flame from below;" therefore, experiments made in this way prove nothing in regard to the operations of nature. Any one in the least acquainted with the literature of the subject, knows that Pouillet was mistaken in the deductions he made from his experiments, but this does not prove that, for instance, Matteucii was mistaken when this eminent Italian physicist found that if using moist earth and sunshine, in place of brass plates and flames, electricity was developed by evaporation.[2] It is not enough to use delicate and elaborate modern appliances; they do not make up for sound judgment and circumspection in regard to the other complicated circumstances under which nature operates.

In the second paragraph of his reply, Prof. Blake asserts that "*quiet evaporation* is the only kind of evaporation occurring in nature." This assertion simply astonishes me. Does he call the evaporation of a storm-tossed ocean a "quiet evaporation"? Does he consider as such the forced evaporation from the millions of leaves of the trees, when a hurricane sweeps through the forests? If evaporation is not here the cause of electric development, may it not be the friction of the air on the surface of the water, or on the leaves, as has been proved by Reich[3] and Riess,[4] that in the Pouillet experiment with the hot crucible and water in the spheroidal condition, it was friction, and not evaporation, which generated the electricity developed. This, therefore, may be another source of electricity, which, however, it would be difficult, if not impossible, to verify by experiment on a small scale.

Any one who, during a hurricane, has been in mid-ocean and observed how the tops of the waves are curled over by the wind, must have become convinced that there is considerable friction between air and water; the existence of this friction is evident even when a gentle breeze ripples the surface of a quiet lake, and further demonstrated by the well-known fact, that it may be corrected in the same way that we correct the friction between solids, namely, by a lubricator; hence the quieting influence of oil poured upon the surface of water agitated by the wind.

Query: Does perhaps the gaseous envelop surrounding our partly liquid and partly solid globe, almost continually moving and rubbing the terrestial surface, constitute a gigantic friction machine?

I do by no means consider induction as the only source of atmospheric electricity, as Prof. Blake appears to infer from my remarks. Previous to my explanation of induction, I spoke of conduction, in case a cloud or mist is in contact with the earth, and afterward I mentioned induction as a most prolific source of atmospheric electricity, by no means asserting that this would explain all; to the contrary, I said at the beginning of my remarks that I "admitted that the existing theories upon the origin of atmospheric electricity are not fully satisfactory to explain *all* the details of the phenomena exhibited." But I meant to say that I consider the theory of Peltier as the most satisfactory, and that when rightly understood and applied, it will explain many phenomena about which a number of investigators are still in doubt, and appear to have agreed to disagree.

But the main point upon which the professor's defense appears to rest, is that in my extempore remarks I happened not to speak of "convection," but only of "conduction." He infers from this that there is in my mind "a confusion of the scientific distinction between them," and, further on, he says that I "entirely failed to grasp the difference between convection and conduction." I answer, that he entirely fails to grasp the relation existing between them, which is so intimate that most of what I have said of conductibility may be said of convection also, and Prof. Blake commits a grievous error when he says that my remarks about "the conductibility of watery vapor have no bearing at all upon the subject." I claim that *in order to make convection possible, the substance which is to convect the electric charge must have the capacity to hold electricity;* and I claim also, that the air heated in the way described by Prof. Blake, and as reported by Helmholtz to the Royal Academy, notwithstanding it was charged with some watery vapor, is so poor a conductor as to make it unfit to acquire a charge of electricity; consequently it could not convect it. Even their own experiments, as described, prove this, because if it had been a conductor (what I tried to explain it could not be), the moisture between the two brass plates would have communicated the electricity to the upper plate, and *it would have become electrified by conduction, if not by convection. The result of the experiment would have been all the same.*

I should like to be informed by Prof. Blake, how, in case his experiments with the brass plates had succeeded, he would have demonstrated that it was by *convection* alone and not by *conduction* that the upper plate became charged.

It may be well to quote some authorities here, in order to settle the matter about the resistance of air against electrification. It is a principle at present agreed upon that *pure air has no electricity whatsoever and is incapable of conducting or retaining it*;[5] consequently it cannot convect it. Or stated in connection with Peltier's theory, it has been said that: "*dry air is not electrical by itself, the earth has a resinous tension, and the* (upper highly rarefied) *space a vitreous tension*."[6] Therefore, the condensed air along the earth's surface forms a neutral insulating layer, separating the electricity below from that above. Sir William Thomson compares it to a huge Leyden jar, of which the earth's conducting surface is the interior lining, the condensed air the dielectric, and the conducting upper rarified stratum of air the outer coating, while the interior of the jar is charged with negative electricity, of which the positive charge of the upper stratum is the electropolar complement.[7]

I feel inclined to interpolate here the remark that if it were not for this insulating property of the condensed air we live in, mankind would forever have remained in ignorance of anything relating to static electricity (and, consequently, dynamic electricity also), because we would be unable to retain the static charges—they would diffuse themselves as soon as developed. It follows from this that when in winter our experiments with this kind of electricity are very successful, we are wrong in saying that there is much electricity in the air; it is exactly the reverse, because when the air is incapable of becoming charged the insulation of our apparatus is more perfect. In summer, when evaporation is active and the air moist, the insulation becomes defective because the air becomes slightly charged, and experiments depending upon insulation are not satisfactory.

We know that ordinary air, even on a so-called dry day, contains some moisture, and that absolutely dry air exists only temporarily in some exceptional localities, still we know that the ordinary dry air notwithstanding it contains some moisture, is by no means a good conductor, but belongs rather to the insulating substances, and what I attempted to point out in my remarks was, that moist air, heated above the dew point, is practically equivalent to dry air, and will neither transmit electricity by conduction nor by convection, and I repeat with a slight modification what I said in my remarks, namely: *if we wish to evolve a vapor which will convect electricity, the temperature should not be too high, the air of the room moist, and the barometer low.* This is the case in nature when a mist becomes negatively electrified by contact with the earth's surface; and I stated distinctly that in such a case the negative charge will accumulate *on the upper surface* of the mist. If its conductive contact with the earth becomes imperfect while its upper portions retain their full capacity of conductivity, by reason of lower temperature and lesser atmospheric pressure, the lower portions of the mist must show traces of positive electricity, generated by induction from the negative terrestial surface, like the lower surface of clouds, must have a tendency to show positive or less negative electricity, while the upper portions are strongly negative. Prof. Blake in his reply misapprehends my meaning because he has confused the upper and lower portions of the mist, when he says that, according to my remarks, "this conducting mass (the mist) should be negative, while it has always been found to be positive." I remind him that in order to find the negative charge the observer will have to ascend as high as the conductivity of the mist extends,[8] while on the earth's surface no electricity will be perceptible. These are my words, and I add now that seldom or never a negative charge will be found in the lower portions of a mist, but either no charge at all according to the law of conducting spheres, as I have stated in my remarks, or a positive charge, in case the conductivity of the lower surface layers is impaired.

If such a mist ascends, and mingles with the clouds above we have pure convection on a large scale. In order now to establish convection on a small scale we must secure the conditions upon which, in my remarks, I have laid so much stress, and of which I hoped that the importance would be comprehended and not passed over in silence. I must therefore state them again; they are: *the capacity of watery vapor to conduct and convect electricity depends upon its condition in regard to the dew point; when temperature and atmospheric pressure are below the dew point the misty vapor can hold, conduct and convect electric charges, witness the clouds; but when temperature and pressure are above the dew point, the mistiness disappears, the air becomes clear and comparatively dry, it will almost entirely lose its electrical capacity, and it will neither hold, conduct nor convect.*

The latter conditions were those under which Prof. Blake's and Helmholtz's experiments were made, and they illustrate forcibly the results of conditions, under which we cannot expect either conduction or convection. In order to be complete, the experiments should also be made under the conditions which I have mentioned, and which are those which frequently prevail in nature when the electricity of the earth's surface ascends by conduction and by convection, which undoubtedly often restore the electrical equilibrium downward as well as upward, both unperceived, and only ascertainable by special appliances, which the older investigators possessed as well as the later ones. It is true the appliances were not as refined, but it should not be lost sight of that, for instance, the operation of an old fashioned gold leaf electroscope is as sure an indication of the existence of electricity as is that of Helmholtz's quadrant electrometer, and that an old fashioned frictional machine as used 25 years ago in my experiments in this line, produces electricity as well as a zinc-water-copper battery. When properly managed it gives a kind of electricity much more similar to that of the atmosphere than is produced by the latter, which I do not consider so well adapted for the purpose, and would not use in this case notwithstanding I possess three of them of 2,560 elements each.

De la Rive mentions a fact showing the difference between this kind of electricity and that of the atmosphere. He states that a delicate galvanometer with 2,400 windings, carefully insulated, and which therefore would give very decided indications with the 500 elements of the zinc-water-copper battery, used by Prof. Blake, did not enable him to perceive sufficient atmospheric electricity so as to recognize daily or yearly periodicities. It was only at the approach of thunder clouds, with rain and snow, that decided indications were perceived.[9] When we consider that the old style electroscope, as used for static electricity, in connection with proper condensers, gives very decided indications about daily variations in the electrical conditions of the atmosphere, the greater similarity of the latter with ordinary static electricity becomes evident.

I cannot omit here, expressing my regret that there is at present a tendency to treat older experiments as worthless, because they were performed with less pretentious instruments than exist at the present day. I wish that the average physicists would follow the example of the average microscopist, who, armed with the magnificent immersion lenses and other appliances of the present day, still give due praise and credit to the pioneers in their branch of science, such as Leeuwenhoek, Lieberkuehn, Lyonet, Ellis, etc., for what they have accomplished by their less perfect instruments.

My first experience in atmospheric electricity dates as far back as 1829, when I assisted General Kraaijenhoff[10] in his investigations upon this important subject. Through an opening in the roof of his palatial residence, he had a very long insulated lightning rod erected, which could at will be connected to the ground, or with the proper electrical apparatus known at that time, and with which the attic story was well provided, while the whole arrangement left nothing to be desired in regard to peculiar convenience and perfect safety. I frequently amused myself there with boyish delight repeating with atmospheric electricity the experiments then known and usually made with frictional electricity. In the meantime I became powerfully impressed by the sight of the enormous quantities often

10. This eminent Dutch engineer and physicist, who had during his active life occupied various exalted positions, such as inspector of fortifications under the first Napoleon, and as minister of war under his brother, Louis Bonaparte (once King of Holland and the father of the late Napoleon III.), devoted the latter years of his eventful life quietly to the advancement of physical sciences, especially in regard to the then already rapidly extending branch of electricity. The French royal academy awarded to him the first prize for his extensive essay on the advantages incident to the study of electrical science. This work, first written in Latin, was afterward translated into French and Italian. In his younger years he wrote a book entitled "Electrical Physics," and later (1886) published a treatise with instructions on the proper construction of lightning rods, he having been the first to erect effective and reliable lightning rods in different parts of the western portion of the European continent. In 1782 he directed the placing of a lightning rod upon the great church spire of Doesburg, Netherland, which tower before that time had every year been struck by lightning and damaged, but which afterward was found to be perfectly proof against such calamities.

discharged and beyond our capacity of computation, and still more the occasional high intensity of discharges equivalent to millions of volts, all of which are only weakly approached by our most powerful modern arc-light dynamos. It also impressed me in early life with the conviction that it is very risky to deduce positive opinions about the gigantic operations going on in the atmosphere, from the experiments we make with our static machines, which are comparatively mere toys. Still I admit, of course, that those experiments have initiated man into one of the most important secret agencies of nature, and solved problems which have been mysteries to our ancestors, and are still so to the ignorant.

During more than 50 years that I have been lecturing on physics, I have of course taught the phenomena attending the propagation of electricity by convection and by conduction, and during the last 20 years have laid particular stress upon the fact that convection and conduction through air is facilitated, by bringing temperature and pressure below the dew point, as explained above, and I have occasionally illustrated this by placing moistened earth under the bell-jar of an air pump, and exhausting slightly until the well-known fogginess appeared, always seen at the beginning of exhaustion, when sufficient moisture is present in the bell-jar. It is then found that the electricity is conveyed (both by conduction and convection) to the upper plate, which it is better not to have smoothly polished but rough; better still is a wet sponge as it is more similar to a cloud, and will contribute its share to make the air sufficiently moist so as to better enable it to conduct and convect. If the experiment is made with dry earth and dry air it is necessary to exhaust considerably and substitute a ground connection for the electroscope; then the familiar luminous phenomena will be seen, known as the aurora tube experiments, similar to the Geissler tubes, etc. In this case the electricity is visible in the dark; in the former case, when passing through air oversaturated with moisture, it is invisible but manifests itself on the electroscope connected with the upper plate or wet sponge.

Another point of which I have not spoken yet, and which I never omitted to instruct my class in, was this: like *conduction* of the air is aided by saturating it with moisture and keeping it cool, so *convection* through air is facilitated by projections, especially by points, so that air which otherwise would not convect electricity, can be forced to do so by a proper form of the electrically charged conductors. Various lecture room experiments illustrate this, and nature does it in the St. Elms fire, in pointed lightning rods, often also with the tops of the masts of ships, and occasionally with the tops of trees, and even with the ears of horses and the raised hands of men. [11] Dryness of the air is a condition for these phenomena, as proved by the fact observed, that wetting some of the objects causes the light emanating from them to disappear; it does not, of course, stop the electric discharge, but the watery vapor makes it invisible.

If now we do not take advantage of this property of projecting points and do not use something equivalent, in case we wish to convect electricity, but instead of this, use smooth brass plates, we commit an oversight of nature's methods in the experiments under discussion.

The resistance offered to convection by flat circular surfaces is forcibly illustrated in the electrophorus, in which the charged lower surface holds its negative electricity, notwithstanding the absolute contact of the metallic cover, out of which, by the ordinary operation of this instructive apparatus, a great number of positive charges may be obtained *by induction*, far surpassing in their totality the original negative charge, and this without diminishing the latter.

This leads me to the last point in the reply, which I have to notice. I have stated a theory (which is not mine exclusively), that the earth may charge clouds by induction, and that these may charge one another, and are known even to charge locally the terrestrial surface by induction. [12] Prof. Blake attempts to dispose of this theory by mentioning the observations with Sir W. Thomson's water-dropping collector, which indicates a low potential of the earth's charge, and winds up the paragraph by saying: "The atmospheric electrification, which, according to the remarks, is the *induced* charge, must enormously surpass the earth's charge, or the induced exceed the inducing electrification, which is absurd."

This is a very thoughtless expression. Old as well as modern experiments abound with illustrations that the potential of weak charges may be enormously intensified in various ways; also those obtained by induction may be again intensified by induction. The condenser of Volta is based on this principle, as is also the duplicator of Bennet improved by Cavallo, which was known more than a century ago; while with the improved multiplicator of Nicholson [13] the merest trace of an electric charge can be increased enormously by inductive action.

Such and similar apparatus was a century ago successfully used for the determination of the electric charges of rain, snow, hail, etc. [14]

The Holtz machine and its modifications (which may be considered as improvements upon the old-fashioned revolving multiplicators of 100 years ago) show how, by the aid of inductive action and air friction, the original slight static charge (made by a small piece of vulcanite rubbed by a proper material) may be increased enormously; while the Ruhmkorf coil is an illustration of how a weak dynamic current of a few insignificant elements may be raised to a very high potential, surpassing that of the original, thousands of times.

Biot gives formulæ by which he proves the enormous increase of potential toward the extremities when a charged conductor is elongated. [15] If we apply this to a weakly charged cloud, and suppose it to be stretched out by winds or by the attraction of clouds charged with an opposite electricity, we find here another possible source of increase of the potential.

The total disregard of the many ways by which weak charges of clouds may be increased to a high potential is so much more surprising from the side of Prof. Blake, because at the end of his reply he mentions the theory of Taite in regard to "the increase of potential by the agglomeration of the vapor particles into drops, so as to form clouds and rain, according to the law of the dependence of the potential of a sphere upon its radius," and he says that it would "be plausible if we can only account for the original electrification of the minute vapor particles in the air." According to what I have explained, he has only to make these vapor particles vesicular, that means, reduce them to the state of mist, either by cold or diminished atmospheric pressure, or both; then they will hold, conduct and convect the terrestrial charge upward.

I find, just now, that Du Moncel expresses a similar opinion when he says that "water diffused in the air in the vesicular state (the state of mist), is a secondary conductor, which means a character of inferior conductivity, which, however, permits that when placed between two charges of opposite electricities, the discharge will take place at much greater distances than through ordinary air." [16]

As soon as I became convinced of the correctness of the theory stated by Mueller and referred to above, *that clear transparent air cannot hold electricity*, it became evident to my mind that the potential of a cloud can be enor-

mously increased when it becomes smaller by the dissolution of the parts constituting its exterior boundaries, into clear air. If such air cannot hold electricity, every dissolving particle must convey its charge to the neighboring one which remains in the state of mist or cloud, and this process will go on in the apparently contracting cloud until the potential of the charge becomes so strong as to be able to leap over the distance separating it from the nearest conductor, when we will have a stroke of lightning. This explains also the thunder and lightning explosions occasionally observed from an apparently clear sky; they result from a disappearing charged cloud.

It was in 1873 that I first read in the third edition of Mueller's "Kosmischen Physik," published in 1872, this principle about the incapacity of air for electric charges, and applying to it the results of my experiments, referred to above, and which I had made in 1861–1862, while occupying the chair of Physics in the Cooper Union, New York, I conceived the theory just mentioned, while in 1880 I found that it was very similar to that of Taite, published in *Nature* for September of that year; only what I conceived to be the case in the limit of a cloud, Taite beautifully considers in every individual vapor particle when it becomes a minute rain drop; but Taite did not start from the fact that the air has no capacity for electric charges, which lies at the basis of my theory about the cause—how the potential of a cloud may be raised as a whole.

There is a well-known little lecture-room experiment, which I always exhibit in this connection. It consists of employing an insulated cylinder upon which a piece of conducting cloth can be wound and unwound; an electroscope attached to the same shows a remarkable increase of potential, when, after charging the cloth, the surface is decreased by winding it upon the roller, and *vice versa.*[17] The piece of cloth represents here the cloud of which the potential is raised by decrease of surface.

While writing the above a great deal more comes to my mind, which I should like to add, were this article not already becoming too long; but as the subject is so enormous in extent, physically as well as mentally, and as it has seriously occupied my mind, off and on, for nearly 60 years, I may return to it in some following number. It is perhaps well that the stimulus of self-defense against Prof. Blake's attack has induced me to take more trouble than I otherwise would have taken in bringing some of the results of my long and quiet labors before the readers of the Electrician and Electrical Engineer.

THE MAMMOTH TANGENT GALVANOMETER AT CORNELL.

BY W. A. ANTHONY, PH.B.

The tangent galvanometer described in this paper was constructed to serve as a standard instrument for the measurement of currents of all magnitudes, from one milliampère to 250 ampères. The writer had long felt the need of such an instrument in connection with investigations in progress in his laboratory, and for the purposes of experiment and instruction in the course in electrical engineering, as well as for standardizing the commercial instruments used for measuring electric lighting currents.

Plans and drawings were in progress when the writer was invited to take part in the dynamo tests at Philadelphia. In the progress of that work many valuable hints were obtained as to the requirements which such an instrument should meet, and in subsequently completing the plans the endeavor was to meet all the requirements and fulfill all the conditions that experience had shown to be important.

The most essential conditions were: that the dimensions should be such that they could be obtained with great precision, and at the same time make it unnecessary to consider the small corrections due to the length of the needle; that it should be possible to read the deflections upon a *graduated circle* to fractions of a minute; that the coils should be of such dimensions and capable of such combinations as to give a variety of constants; that the needle should be as nearly as possible "dead beat," and that the instrument should contain within itself the means of obtaining the horizontal intensity of the earth's magnetism.

For the measurement of heavy currents it was necessary that the coils should be of wire sufficiently large to avoid heating and consequent alteration of their dimensions.

The plan upon which the instrument was finally constructed is that of Helmholtz. There are three pairs of equal coils—the coils of each pair being at a distance apart equal to their radii, and symmetrically placed with reference to a central point where the needle is located.

The coils for heavy currents are four in number, each a single turn of copper rod, 1.9 cm. in diameter. The diameter of one pair of coils is 200, and of the other 160 centimetres. (The dimensions given in this paper are those aimed at in the construction of the instrument. The actual dimensions have of course been carefully determined.) The constants of these coils are roughly: for the four in series, 8; for the two larger, 19; for one larger, 38; for the two larger, used differentially with the two smaller, 75; and for one large and one small coil used differentially, 150 ampères. Hence currents of from 4 to 250 ampères can be measured by deflections of the needle between 25 and 60 degrees.

These coils are mounted on a frame of cast brass accurately turned and adjusted. The currents are led to and from the coils by means of a rod surrounded by a tube of copper carefully insulated from it, and extending to a distance of about three metres from the coils. There the conducting wires are connected. These consist of copper wire, 1.17 cm. diameter, insulated with a thick covering of braided cotton saturated with paraffine, and the wires of each pair are twisted together. For smaller currents two coils, about 150 cm. diameter, of two wires, 2 mm. diameter each, were wound in grooves in the frame; both wires being wound at the same time, so as to occupy as nearly as possible the same position relative to the needle. When coupled in series, they form a coil of 36 turns, in six layers of six turns each. The two wires of the same coil, used differentially, produce only a barely sensible effect on the needle where one alone would cause a deflection of 50°. The object of this construction was to have the means of testing the accuracy of the adjustments of the galvanometer.

When the needle was adjusted to the middle point of the line joining the centres of the coils, no deflection was produced on reversing the current in the fine wire coils of each side used differentially; when if the needle was moved half a millimetre toward either side, such a reversal would produce a deflection of 10 minutes.

The same is true of the two smaller coils of copper rod. The two larger coils, however, gave a deflection, with the same current used on the smaller coils, of 9 minutes, owing to the fact that these two coils were not of exactly the same dimensions. The constants of these two coils, computed from the measured dimensions, are 37.828 and 37.818, a difference of a little more than one four-thousandth. This test of the accuracy of the adjustment of the instrument is, therefore, a very delicate one.

The needle consists of several pieces of fine steel wire cemented parallel to each other on a thin circular disc of aluminum, and cut to such lengths that their poles are very nearly in the circumference of a circle three centimetres in diameter. This construction was adopted to produce a powerful system whose poles could not be displaced by the action of a transverse field, which is a serious

Digitized by Google

source of error in needles of considerable bulk, especially in the "bell-form" magnets of the German instruments. The circular form also tends to eliminate any error due to the dimensions of the needle. The needle is placed in a cavity in a copper block, which renders it very nearly "dead beat." It is suspended by a fibre of silk, with adjustments for centreing.

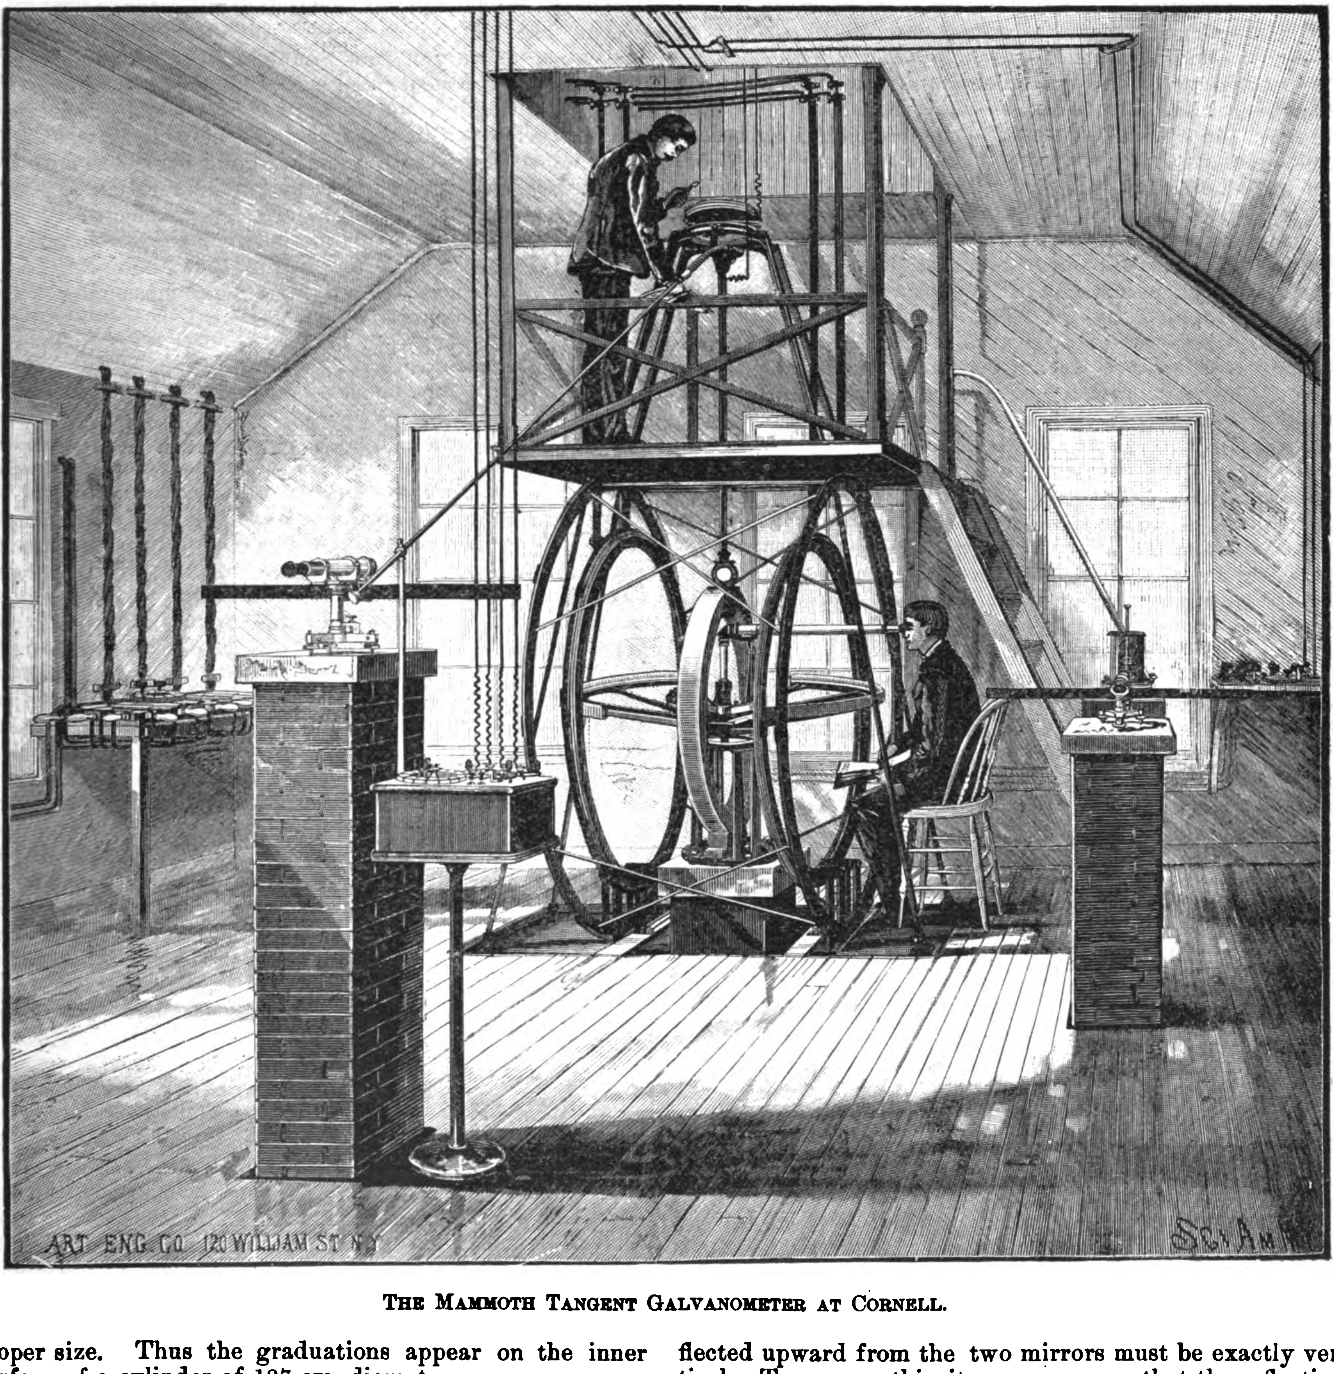
The divided circle on which the deflections are read was made by graduating thin brass strips and springing them into the inside of a cast brass rim accurately turned to the proper size. Thus the graduations appear on the inner surface of a cylinder of 127 cm. diameter.

For reading the deflections of the needle, two mirrors are rigidly connected with it at angles of 45° with the vertical, and so placed that light from opposite points of the graduated circle is reflected vertically through the tube that encloses the suspending fibre, to a rectangular prism, by which it is reflected horizontally into the observing telescope.

By this arrangement, images of opposite portions of the divided circle are seen simultaneously in the field of view; and by taking both readings, any error from eccentricity is eliminated.

The observing telescope, the block which surrounds the needle, and the support of the suspending fibre, are all carried upon a vertical conical spindle, free to turn in a socket in the centre of the graduated circle.

In the ordinary use of the instrument, the telescope is fixed in position. In this way readings may be very rapidly made, but in order that they may truly represent the deflections of the needle, the axis of the pencil of light reflected upward from the two mirrors must be exactly vertical. To secure this, it was necessary that the reflecting prism in front of the telescope should be adjusted to reflect such a pencil along the axis of collimation. This adjustment presented some difficulties, but it was finally accomplished by making the axis about which the telescope revolves accurately vertical by means of a delicate level, then, the copper block and needle being removed, a point on the base of the instrument could be seen through the hollow conical spindle, and the prism was adjusted till a point was found whose image remained fixed upon the



THE MAMMOTH TANGENT GALVANOMETER AT CORNELL.

Digitized by Google

cross hairs of the telescope as this was revolved about the vertical axis. The needle being now replaced, the mirrors attached to it are adjusted to bring the graduations into the field.

The readings have still to be corrected for the refraction of the glass sides of the box which protects the mirrors from currents of air, and for the torsion of the suspending fibre. The necessity for these corrections may be avoided by turning the telescope, and with it the box enclosing the mirrors, and the support of the suspending fibre, through the angle that the needle is deflected, before taking the reading. For this purpose a pointer is attached to the support of the telescope, and moves with it in front of the graduated circle. By turning the telescope till this pointer appears on the cross hairs, the corrections spoken of above, and all errors due to want of accurate adjustment of the optical part of the apparatus, are avoided.

The instrument is mounted in a building free from iron or other causes of irregularity in the earth's magnetic field; but since the intensity of this field is continually varying, it is necessary that it should be determined whenever the instrument is used for any work requiring high precision. This is accomplished by the method proposed by Sir Wm. Thomson. A coil one metre in diameter, of 100 turns of No. 18 copper wire, wound in a groove accurately turned in a light brass ring, is suspended by a single wire of phosphor-bronze, about two metres in length, from a torsion head whose circle, 10 inches in diameter, reads to 10 seconds. This coil is so placed that the needle is at its centre. A mirror is fixed to the coil, and a telescope and scale at a distance of about three metres, provides for the precise determination of any movement. To observe for H, a current is sent through the coil sufficient to produce a convenient deflection of the needle. The torsion head is now turned to bring the coil into the magnetic meridian. The movement of the torsion head required is about half the deflection of the needle. The determination of H, of course, depends upon a knowledge of the torsional force of the wire supporting the coil. It is important, therefore, to determine this force and its changes from variations in temperature or other causes, with extreme precision. The suspended coil weighs about five kilograms. The wire selected will support 25 kilograms without breaking. Its torsion force is not likely, therefore, to change from any stretching due to the weight of the suspended coil. For the determination of the torsion force, an inertia cylinder was constructed, having the same weight as the coil and arranged to be suspended *in the place of* the latter, with the axis of the cylinder in line with the suspending wire. To insure homogenity, the cylinder was made from discs of sheet brass. Its moment of inertia is upward of 38,000 c. g. s. units. That of the mirror, which is 54 mm. diameter and 3 mm. thick, is only 56 units. The hook and other parts of the suspending apparatus are so small that their moment of inertia cannot possibly amount to 10 units, and this might, with very little error, be omitted. It has, however, been estimated as nearly as possible, and allowed for. The time of vibration of this cylinder has been determined by upward of 100 observations, covering such ranges of temperature as have existed during August and the first week of September. The time is about 16.8 seconds, and the determinations for all amplitudes, from a few minutes to 90 degrees, never vary for the same temperature by more than a few ten thousandths of a second. The law of variation for temperature has not yet been deduced, but the observations indicate no irregularities.

To determine whether a current passing through the wire would produce any effect on the force of torsion, a fine platinum wire, filed to a sharp point, was attached to the centre of the bottom of the weight and allowed to dip in mercury; by this means a current somewhat larger than the maximum that could be used upon the coil was sent through the wire. No difference in the time of vibration could be detected, whether the circuit was closed or open, but an unexpected result was manifested: Although the wire was fine and exactly in the axis of rotation, and dipped only 2 or 3 mm. into the mercury, it offered such a resistance to the motion that the weight would scarcely continue in vibration for two hours, while with the mercury removed the amplitude was still considerable after 48 hours vibration. With the point in the mercury as the amplitude diminished, the time of vibration diminished until it was more than three hundredths of a second less than the normal amount for that temperature.

The force of torsion known, the observations for H are the work of only a few minutes. The extremely slow vibration of the suspended coil made the operation at first a very tedious one, but by the use of variable resistances, and suitable keys in the circuit of the coil, it was found possible to adjust the torsion head and bring the coil very quickly to perfect rest in the magnetic meridian.

The instrument can also be used as an electro-dynamometer by dividing the current between the stationary and suspended coils in such proportion that their differential effect upon the needle is null, and then measuring the effect of these currents upon each other.

Physical Laboratory, Cornell University,
Ithaca, N. Y., September, 1885.

THE TELEGRAPH SITUATION.[1]

PUBLIC attention has been again drawn to the situation of the telegraph lines of the country by rumors of a settlement between the Western Union Telegraph Co. and the telegraph organization conducted by the Baltimore and Ohio R. R. Co. The controversy on this subject between Mr. Garrett, of the Baltimore and Ohio, and the representatives of Western Union, Messrs. Field and Green, does not leave a very clear impression as to its actual origin and merits. The first rumors of an arrangement of the existing telegraph competition arose simultaneously with the announcement of the Vanderbilt-Pennsylvania treaty. It was evidently part of their arrangement that the joint influence of the contracting parties was to be exerted in preventing the Baltimore and Ohio R. R. Co. from obtaining a line into and terminal facilities at New York. The New Jersey Central R. R. was the road which the Baltimore and Ohio have intended to use for this purpose. The story at once took the shape that Mr. Jay Gould, as representing the present Western Union management, had obtained a controlling interest in Jersey Central, and was in a position to turn the road over to Baltimore and Ohio in return for their withdrawal as a competitor to the Western Union in the telegraph field. Mr. Cyrus W. Field, an active director of Western Union, and Mr. Robert Garrett, president of the Baltimore and Ohio R. R. Co., were in London, and it became noised about in Wall street that negotiations were being conducted between them, as representatives of their companies, through the mediatorship of Mr. John Pender, M. P., who is in a manner connected with the Western Union company. It was even stated that they had progressed to an agreement by which the Baltimore and Ohio wires were to be leased to the Mutual Union Telegraph Co., an organization owned by Western Union. There is nothing in the existing conditions which rendered this improbable. The general belief, which does not seem far out of the way, is that the Western Union system, both as to extent and capitalization, has reached a point where further severe competition cannot fail to prove disastrous to its earning capacity. The vigorous attempt in which it had just been engaged to cripple one of its small competitors, the Bankers and Merchants' Telegraph Co., also tended to confirm the impression that its controlling influences were disposed to use every exertion to remove the competition of its chief rival. The reported

1. *Bradstreet's.*

Digitized by Google

agreement, coupled with further statements that Mr. Garrett was disappointed with his telegraphic experiment, and that there was a deficit to the Baltimore and Ohio R. R. Co. of $50,000 per month from the operation of the wires, was widely circulated and found considerable belief. Mr. Garrett was cabled, and authorized a denial that any such arrangement was contemplated. The circulation of the reports, in spite of more emphatic denials on his part, finally resulted a few weeks ago in the publication by both parties of the cabled correspondence. There are two views to be taken of the matter so far as it has been made public. Mr. Garrett's denials, and those of Mr. Bates, president of the Baltimore and Ohio Telegraph, that they have any intention of entering into a combination of any kind with Western Union, and that they propose to maintain the independent attitude of the Baltimore and Ohio Telegraph, is entitled to more weight than is usually accorded to utterances of this nature. It would, therefore, seem that the matter is the result of a characteristic indiscretion on the part of Mr. Cyrus W. Field. On the other hand, there is still a possibility that while the reports are premature, they represent the first stage of a negotiation by which the competition of the Baltimore and Ohio lines may ultimately be done away with, either by absorption or pooling with Western Union.

It is this possibility which brings the telegraphic question again into prominence as a pressing social problem. To recount the growing importance which the telegraph bears in our national development and existence is not requisite. Considerations of the greatest magnitude demand that electric communication should attain the maximum of speed and efficiency with the minimum of cost to the individual. So far it has been left to private enterprise, which in a measure has met the requirements, but whether it can supply the increased demands of the public under its present organization, is questionable. It is particularly doubtful whether in the matter of cost of the service the needs of the public are sufficiently conserved. They certainly would not be in the absence of competition.

The Western Union Telegraph Co. is of all the corporations of the country the one having the most extended field of operations, and the one with which the greatest proportion of individuals are daily brought in contact. It extends into every state and territory, and has offices in every city or town of any importance. Its development as a system of wires has kept pace with that of the railroads, with which it has been its policy to maintain the closest alliance. The greater proportion of its lines run along the railroad tracks. Under varying conditions the general form of the contracts with the railroad companies is that Western Union shall maintain and operate the telegraph, having exclusive right to commercial messages at all stations, free transportation of men and material for the erection and maintenance of its wires, and room for telegraph offices in all stations. The railroad company, on the other hand, receives the use of such wires as may be necessary in the direct operation of its road and running of trains, together with a certain amount of free telegraphy for the general business of the railroad company. In some instances part of the expense of the telegraph is met by the railroad, but the general features of the agreements are as stated above. To hold this connection with the railroads has been the fixed policy of the Western Union company. The greater proportion of the roads are included in such arrangements.

As a corporation it grew up from a small organization, and by a process of absorbing other companies, and leasing or erecting new lines in connection with the railroads, its system commenced, about the period of the civil war, to assume something like its present extension. From time to time other competing companies were formed, but by various means they were all absorbed, and their lines made part of the Western Union system. About 1878–9 it met the most severe competition that it had experienced up to that time. Mr. Jay Gould had been interested in a company, the Atlantic and Pacific Telegraph, previously absorbed by Western Union under a pooling arrangement. Apparently he had formed his own ideas of the vulnerability of the latter. He therefore became the prime mover in the formation of the American Union Telegraph. This organization was largely modeled upon the Western Union, and endeavored to follow the same tactics. At that time there remained a considerable mileage of poles and wires still owned by various railroad companies, and either operated independently or merely held by Western Union on terminable leases. Wherever it could be done, American Union secured control of these lines, and by the erection of a considerable number of new ones, soon had a system which reached a proportionately greater number of points and covered more territory than any previous competitor of Western Union. The competition between the companies was of course fierce, and resulted in a substantial decrease of rates over all the territory into which it extended. Western Union was at that time under Vanderbilt control. Its total stock amounted to $41,000,000, while its lines consisted of some 85,000 miles of poles and 230,000 miles of wires, with 9,000 offices. The stress of competition upon the company, however, resulted in the retirement of the Vanderbilt interest in the latter part of 1880, and the securing of the control by Mr. Gould. Immediately after, in January, 1881, a consolidation was effected by which the lines of the American Union, as well as the Atlantic and Pacific (which had been maintained as a separate organization, although pooled with Western Union), amounting together to about 100,000 miles of wire, were transferred to Western Union. The bonds and stock of the American Union to the amount of $15,000,000 were converted into Western Union at par. The $14,000,000 of Atlantic and Pacific stock was also exchanged at 60 per cent. of its par for Western Union stock, and $15,000,000 of new stock was distributed to the holders of the then Western Union stock. This increased the capitalization of the company from $41,000,000 to $80,000,000; the mileage of poles to 110,000 miles, and the wire to 325,000. The ground was immediately taken by Mr. Gould that, having virtually secured the entire control of all the wires operated in connection with the railroads, no company could ever successfully compete with Western Union. Rates were at once approximately restored, although in some instances the competitive rate had become such a fixed public institution that no change was made.

The natural result of this stock-watering and consolidation was a new crop of competitors. The principal one was an institution known as the Mutual Union Telegraph, which, organized and constructed with vigor, soon had a passable system to most of the important northern and western points. It, however, labored under the disadvantage of having no connection with the railroads, its lines being almost entirely constructed across country. After a short-lived competition it too was absorbed by Western Union, under a guarantee of 6 per cent. interest upon its capitalization of $7,500,000. Two other concerns, the Bankers and Merchants' and the Postal Telegraph companies were also organized and are still in existence, their systems reaching only the large cities north of the Potomac and Ohio rivers. The troubles of the former company are still fresh in the public mind, as well as the characteristic attempt a few weeks ago by the Western Union company to prevent the reorganization of the company and seize its wires. The Postal company presents several new features of construction, the most important being the adoption of a greatly improved form of wire, by the use of which it is expected the process of transmission will be facilitated and the cost reduced. Mr. J. W. Mackay, having entered upon the transatlantic cable enterprise known as the Bennett-Mackay cables, in opposition to the existing cable monopoly to which Western Union acts as a feeder, found it neces-

Digitized by Google

sary to have control of a telegraph system to all important points connecting with his cables. Some time ago he became heavily interested in the Postal company. The financial organization of the concern was, however, defective, its capitalization having been upon an inflated basis, and its growth has consequently been greatly retarded. It is now undergoing reorganization, the intention being to combine its line with those of the Bankers and Merchants' company under the title of the "United Lines Telegraph." The unsatisfactory state of their business renders it impossible to give the mileage of the two concerns with accuracy. It is, however, somewhat less than that of the Baltimore and Ohio Telegraph.

The latter organization is at this moment the only serious competitor of the Western Union. The ownership of the telegraph lines built by the Baltimore and Ohio Railroad Co. along its road had always been retained by the railroad company itself. They had been operated in connection with the American Union so long as it continued a competitor of Western Union. When the consolidation of American Union with the latter company took place the railroad company resumed control of its wires, and soon after resolved upon extending its operations to a field outside of its railway lines, and building its telegraph lines to all important points, independent of the great telegraph organization. The Baltimore and Ohio Telegraph Co. was accordingly instituted as a separate corporation, the control of course being vested in the railroad company. Its lines already extended, with the ramifications of the Baltimore and Ohio railroad, to Cincinnati, Chicago and St. Louis. Extensions have been built to New York, Boston and other points, and different lines acquired when practicable. Among the latter class are the telegraph line along the West Shore and Nickel Plate roads, forming a second line between New York and Chicago. At the present time it has offices at almost every important centre in the eastern and middle states, and in the western states east of the Mississippi, with the exception of St. Paul, while a line via Texas gives it a connection with New Orleans. It has in round figures about 7,000 miles of poles and 50,000 miles of wire, which, in the absence of explicit reports, may be taken to have cost, according to the best attainable information, something less than $5,000,000. This capital has been furnished by the railroad company, and is represented by stock of the telegraph company held by it. The expressed intention of the management has been to extend it to all the remaining important centres of the country. So far as possible it is operated in unison with the Postal and Bankers and Merchants' companies, the three organizations affording each other all possible facilities in reaching points not common to their systems. Indeed, an arrangement was entered into over a year ago by which the three systems were to be pooled as to earnings, and divide the work of extension so that it might be prosecuted more rapidly. This agreement, however, fell to pieces from the inability of the Postal and Bankers' companies, owing to their financial difficulties, to carry out the latter portion of it.

Within these geographical limits the cutting of rates has become severe. The policy adopted by the Western Union is to use the Mutual Union Co., which is owned by it, and which has offices in all the chief cities affected by competition, to meet the cuts made by Baltimore and Ohio. The object of this is to prevent their own company from making too bad a showing. Thus the Baltimore and Ohio rates from New York to Boston, Chicago and St. Louis for messages of ten words are 10, 15 and 20 cents respectively. The Mutual Union rates are the same, but the Western Union rates are maintained at 25 cents to Boston and 50 cents to Chicago and St. Louis. The Baltimore and Ohio rates to Philadelphia, Baltimore and Washington are uniform with that to Boston. Rates to intermediate competitive points have been reduced to the same or proportionate rates. In this way a number of the centres of the country are provided with competitive telegraphy at low rates. The effect upon Western Union's earnings is marked. The assertions made by Western Union officials that the business of Baltimore and Ohio is conducted at a monthly loss of $50,000 cannot be accepted. It has been denied by the officials of Baltimore and Ohio under oath, and the truth apparently is that the latter, if not profitable, incurs but small loss. The reason assigned by Western Union for maintaining rates is that the service which their most perfect organization performs commands the higher rate. It must be owned, however, that the service of Baltimore and Ohio is approaching, if it has not attained, an efficiency approximating that of Western Union. It is by reason of insufficient organization that the low rates made by the Postal and Bankers and Merchants' companies do not appreciably affect the situation.

To non-competitive points, however, no measurable reductions have been made. Southern points, for instance, between Washington and New Orleans, are now altogether dependent upon Western Union service, an organization known as the Southern Telegraph Co., which extended to the leading cities as far as Atlanta, and which had been controlled by Bankers and Merchants', having passed on the collapse of that concern to Western Union. Competition fails to reach over 25 per cent. of the entire telegraph business of the country, which includes a large proportion of the smaller offices. The present 110,000 miles of poles and 450,000 miles of wire operated by Western Union following the lines of railroads enable it to reach all minor points. While it is true that such business is not profitable like the volume of business that comes from the great cities, the public served at such stations have a right to as little discrimination against them as there is in the mails. The policy of Western Union in reference to rates has not always been based upon an enlightened selfishness; indeed, it has practically been to maintain rates at as high a point as the traffic would bear without inviting immediate competition.

These considerations, and many involved with them, constitute a problem the practical solution of which will be forced upon the public. The English example of incorporating the wires into the post-office is not so inapplicable to our conditions as is often asserted. The reduction of the English uniform rate from 12d. to 6d., or 12c., is an experiment in cheap telegraphy, the result of which will go far to establishing a favorable sentiment toward such a programme on this side of the Atlantic. While circumstances here might not favor a complete uniformity in the cost of telegraphic communication over the whole country, an equitable arrangement of the matter is not impossible. Joined to this question is that of the control of the cables, the international importance of which is not entirely appreciated, and which might become the proper subject of ownership by the nations they serve to bind together.

POWER REQUIRED ON ELEVATED RAILROADS.

A TEST of a locomotive in operation on the Third avenue elevated railroad, New York, was recently made by Mr. Angus Sinclair, and described in the *Car Builder;* the engine drawing the usual load of a train of four cars weighing some sixty-six tons, over its route of 8½ miles, making twenty-five stops. The engine weighs 24 tons; cylinders, 11 in. by 16 in.; average indicated h. p., 163.4; running time, 20 minutes; stopping at stations, 22 minutes. The effect of the great number of stops is shown in the fact that the average train resistance reached 42 lbs. per train-ton, which is about five times the estimate of the pull on the draw-bar if the motion of the train could be continuous. The average horse-power exerted by the locomotive, including time and stations, is 77.8; and as there are 63 trains on the road at the same time, there is an aggregate expenditure of 4,901 h. p. on the road. The evaporation of the boiler on the basis of all coal used, without making any allowance, was 7.4 lbs. water per pound of coal; and the hourly consumption of coal was 5.8 lbs. per h.p.

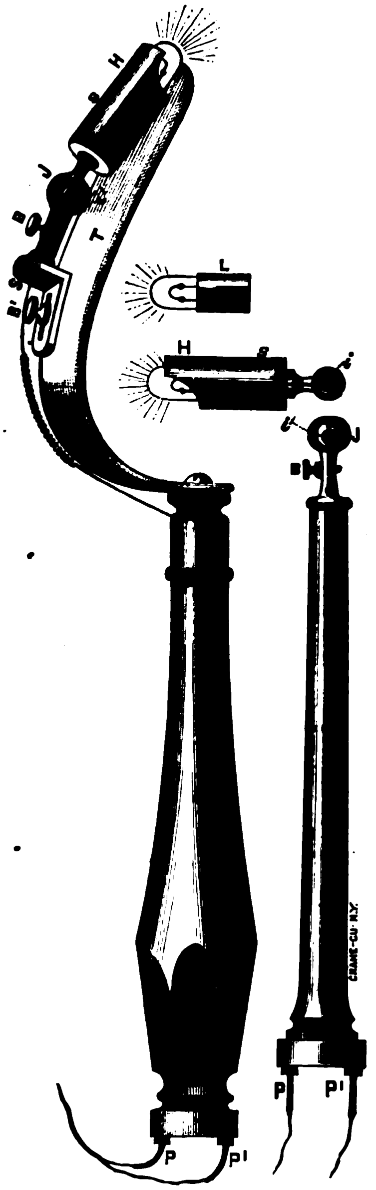
THE ELECTRIC LARYNGOSCOPE.

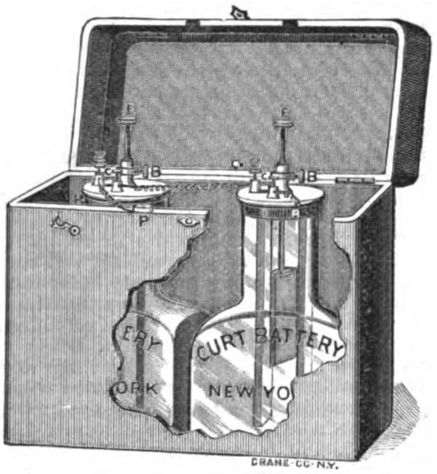
Electricity has gained another apparently permanent foothold in medical practice by the introduction of the miniature incandescent lamp for the purpose of examining such parts of the human body as necessarily require artificial illumination. Either the Laryngoscope or Universal Illuminator, as shown in the cut, are adapted for all possible requirements, and their value in this field must be apparent to every practitioner. In the laryngoscope the tongue depressor, T, is provided with an insulating handle through which pass the conducting cords P and P′. The incandescent lamp L is mounted and set in the shield tube, H, which is a non-conductor of heat. Being connected with



The Laryngoscope—Universal Illuminator.

its support by means of a ball and socket joint, adjustable by set screws, as will be readily understood by its construction as shown in the cut, any desired movement is provided for. By slightly turning the tube H, the circuit may be broken at i^1, when the lamp may be readily removed, and placed in another insulated handle, or in the Universal Illuminator at J. A duplicate mounted lamp, also a mouth mirror with handle, complete this set of instruments, which are packed in a pocket case. All are substantially made and finely finished and are now an indispensable part of a medical or dental outfit.

As yet no battery has been produced so thoroughly adapted to this class of work as the carbon and zinc couple which is usually actuated by a bichromate solution. An improved form of the Grenet battery has been devised by Mr. Meyer, which he calls the "Curt battery," in which he has avoided many of the defects existing in the ordinary portable forms for medical use. The battery has been specially devised to supply the exact current required to develop the full illuminating power of the lamp without danger of destroying the carbon filament. The carbons are corrugated on their inner surfaces, thus enlarging and roughening them. The glass jar is square below and round on the top, holding almost twice the amount of fluid as an ordinary Grenet cell. There is a groove around the upper part holding an elastic ring, over which a rubber cap fits tightly. The carbon clamp is thoroughly faced with platinum, and all parts of the battery are interchangeable. A single charge is sufficient for 150 ordinary applications. Such a battery is of course thoroughly adapted to other uses, such as operating an induction coil, or an electro-magnetic mallet, or charging a secondary battery. The instruments and battery are manufactured by Curt W. Meyer, 357 Fourth avenue.



The Curt Battery.

THAT TEXAS TELEPHONE.

Occasional paragraphs have appeared in the daily papers during the past few months, regarding a wonderful electrical instrument which had been invented by Fred. H. Brown, of Fort Worth, Texas. The descriptions given indicated that it was a simple magneto telephone, which, as is well known, requires no battery to operate it, although better results are obtained by using it as a receiving instrument in combination with a battery transmitter. Considerable interest has been awakened regarding Mr. Brown's invention by reason of the following story which was copied in the New York *Sun* of September 15:

TO REVOLUTIONIZE TELEPHONING.

THE WONDERFUL INVENTION THAT CAME TO A FORT WORTH MAN IN THE DEAD OF NIGHT.

(*From the Fort Worth Democrat.*)

Over three years ago Fred. H. Brown began the work of studying out to an invention an idea which had come to him, that a telephone and telegraph instrument could be made which would work without a battery. For three years he toiled and thought, but seemed no nearer the goal than when he started, until one night in February last, about two o'clock in the morning, he awoke suddenly from sleep and found the invention in his mind. Cold as it was, he jumped out of bed, lighted a lamp, and began to work. In a few months he had perfected an instrument and tried it at home. He at once determined to go to New York; but before his departure sold the right to England to Messrs. George J. Frankel and G. H. Shuttler; to France and Germany to W. E. Keye, who a week later accompanied Mr. Brown east.

The electricians of Mr. Gould and Mr. Mackay inspected the invention carefully, and then the Western Union Telegraph Company and Bell Telephone Company sent men to Washington to see if the method could not be patented; but Mr. Brown had provided against all contingencies, and had patents covering everything. The immense value of the invention was seen by J. J. Safeley, a capitalist, who brought it to the notice of Austin Corbin, a millionaire. He formed a company, and through Mr. Safeley bought the right to the United States for one million dollars, paying $250,000 to Mr. Brown in cash and giving ample security for the payment of $750,000. Mr. Brown returned to Fort Worth early this week, disposed of his property here, and

Digitized by Google

on Thursday night left with his family for New York, where he will reside.

When he left New York bonanza Mackay was negotiating for Canada, which is held by the inventor at $1,000,000. Mr. Brown also brought word that a wealthy man wanted England, and was willing to pay a large sum for it, which will induce Messrs. Frankel and Shuttler to go east in thirty or sixty days to look after their interests. Mr. Keye, the owner of the right for Germany and France, is now in New York, and will leave in a few days for Europe.

When Mr. Brown reaches New York a cable test will be made over 5,800 miles of cable, twice the distance across the Atlantic. Instruments for this test will be completed early next week. A test was made in New York not long ago over 800 miles of wire, and the instruments worked as clear as a bell. In a few days 100 miles of wire will be stretched on Long Island for tests of all descriptions.

As soon as possible the company in New York will get to work and organize sub-companies in all the states, when a revolution in telephoning and telegraphing will surely result.

The invention is a magneto telephone and telegraph without battery—a new system of transmitting the sound of the human voice without using batteries of any kind. Brown has had a hard time perfecting his invention, being refused aid by those to whom he applied. A short time ago Edwin F. Masterson, a lawyer of means, and well acquainted with prominent eastern telegraph and telephone men, saw the instrument tested and at once wrote to a director of the Western Union Telegraph Company and President of the Overland Telephone Company, setting forth the wonderful workings of the invention. The Western Union official went to Gen. Charles A. Tinker and asked him to issue instructions to some experienced manager in or near Fort Worth to have the instrument tested over the Western Union lines and to report to him at once. G. J. Frankel, manager here, received the instructions and ordered the Cleburne manager to assist him. In the afternoon of June 21, at 1 o'clock, Mr. Frankel, Mr. Brown, the inventor, Mr. Masterson, J. H. Murphy, Robert L. Moore, operators, and a newspaper reporter were in the Fort Worth office. Mr. Granger, an electrician, and C. M. Bander, manager at Cleburne, were in the Cleburne office. The batteries on the line were cut off from the wire thirty-eight miles long, and the magneto transmitter and receiver attached at both ends of the line. For two hours the test went on, all parties talking, and J. H. Murphy by tapping on the diaphragm of the instrument telegraphing to the Cleburne operator and receiving an answer in the same manner. The voices of the Cleburne parties were very distinct, and a marked feature was the absence of all foreign noises interfering with and incident to other systems.

The instrument used was composed of two ounces of wire and a half pound of steel, and can be made for twenty-five cents. The transmitter is simply a horse-shoe magnet, either pole being covered with fine wire coiled carefully. The armature is a disc of steel against which the voice is thrown, then transmitted through the magnet to the wire. The receiver is similar, but has a smaller magnet. It is claimed by the inventor that he can transmit the voice around the world or across the Atlantic ocean, there being no limit as far as distance is concerned, all that is necessary being the increasing of the size of magnets.

In order to show how little foundation there is for such gigantic financial transactions as are mentioned in the article quoted above, we have reproduced the patent specification and claims, in order that our readers at least, may satisfy themselves as to the practical value of the invention described.

UNITED STATES PATENT OFFICE.

Fred. H. Brown, of Fort Worth, Texas.

MAGNETO-ELECTRIC TELEGRAPHY.

Specification forming part of Letters Patent No. 324,746, dated August 18, 1885. Application filed March 2, 1885. (No model.)

To all whom it may concern:

Be it known that I, Fred. H. Brown, a citizen of the United States, residing at Fort Worth, in the county of Tarrant and State of Texas, have invented a new and useful Improvement in Magneto-Telegraphs, of which the following is a specification, reference being had to the accompanying drawings.

My invention relates to an improvement in magneto-telegraphs; and it consists in the peculiar construction and combination of devices that will be more fully set forth hereinafter, and particularly pointed out in the claims.

My invention has for its object the transmission of telegraphic or telephonic messages between distant points by means of induced currents produced by the use of permanent magnets and without the use of a battery-current.

The accompanying drawings represent instruments by means of which I am enabled to carry my invention into effect.

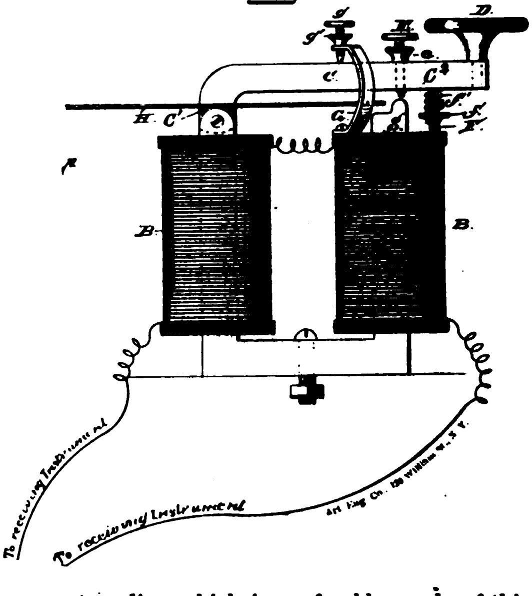
Figure 1 is a side elevation of a sending-instrument. Fig. 2 is a vertical sectional view of a receiving instrument. Fig. 3 is a horizontal sectional view of the same, taken on the line x x of fig. 2.

A represents the sending-instrument, which is composed of a permanent U-shaped magnet, on the poles of which are wrapped the helices of insulated wire B. A key, C, is pivoted to one pole of the magnet, and extends over and beyond the opposite pole thereof, and is provided at its outer extremity with a button, D, similar to the telegraphic keys now in common use. The pivotal end portion, C', of the key is made of soft iron, and the extended arm portion C^2 thereof is made of brass.

E represents an adjusting screw, which is made of iron, and which passes down through the key C, its lower end being normally nearly in contact with the pole S of the magnet. The adjusting screw E is provided with a jam-nut, *e*, as shown.

F represents a brass screw that projects from the upper side of the south pole of the helix. On this screw is placed a thumb-nut, *f*, which is internally threaded to receive the screw, and which is adapted to be adjusted up and down upon the screw F. A coiled spring, f', bears between the upper side of the nut *f* and the lower side of the key, and prevents the screw E from coming normally in contact with the south pole of the magnet. A curved arm, G, is made of brass, and is secured to the upper side of the south helix, and down through the upper end of this arm is passed a regulating or adjusting screw, *g*, which has a jam-nut, *g*, and limits the upward movement of the key.

Fig. 1.



H represents a disc, which is preferably made of thin sheet-steel, and which is permanently secured to the pivoted end of the key and extends horizontally over the poles of the magnet, as shown.

Z represents the receiving-instrument, of which I represents an inclosing-case, which is composed of wood or metal, and is provided with a mouthpiece, K. To the lower side of this case, on its inner side, is secured a permanent U-shaped magnet, the south pole of which is at one side of the inclosing-case, while the north pole is directly in line with the centre of the case and its mouth-piece. On the north pole of the magnet is wound a helix, L, of fine insulated wire, while the south pole is left bare. The ends of helix L are secured to the binding-posts M, and the wires from the sending-instrument are connected to said binding-posts, as shown.

N represents a circular metallic band having projecting points, *n*. This band is placed in the inclosing case, in the upper side thereof, at a suitable distance below the contracted inner end of the mouth-piece, and is secured to said inclosing-case by means of screws, which pass through openings in the outer ends of the projecting points, and secure said points in recesses that are made in the inclosing-case to receive them, as is shown at fig. 3. By this construction an air space is left between the band and the inclosing-case.

On the under side of the band N is secured a disc, O, which is preferably made of thin sheet-steel, and which is acoustically insulated from the band N by a piece of paper or other suitable substance, P, that is interposed between the disc and its supporting band. The south pole of the magnet is in contact with the north pole or outer edge of the magnetized disc, and the north pole of the magnet is directly under the centre of the disc and out of contact therewith.

By this construction it will be plain that the centre of the disc O is free to vibrate. By securing the disc in the inclosing-

Digitized by Google

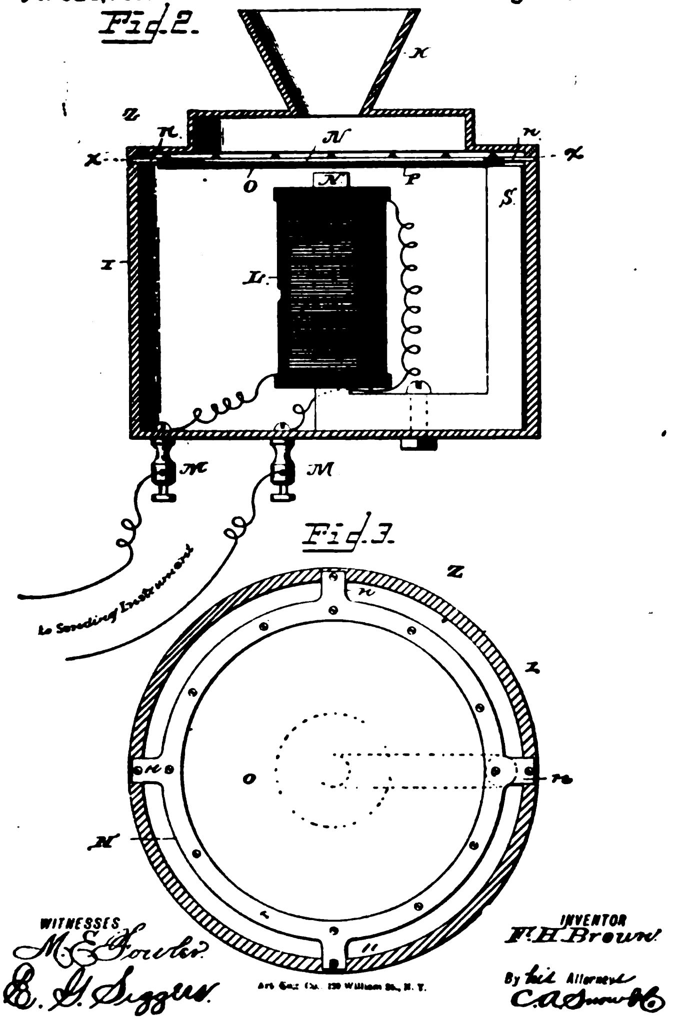
case so as to leave an air-space around the outer side of the disc, between it and the inner side of the inclosing-case, the air-chamber formed by the inclosing-case is in communication with the air-space in that part of the inclosing-case above the disc.

The operation of my invention is as follows: The key of the sending-instrument is operated so as to tap off the dots and dashes used in the telegraphic code (Morse). As the key is depressed it comes in contact with the south pole of its magnet, and thus closes the magnetic circuit, and the jar consequent upon this impact sets the disc, which is secured to the key, in vibration in consonance therewith, and produces a resonant tone. The vibration of the sending-disc induces an electric current instantaneously of great kinetic energy and intensity, but of short duration, which is transmitted through the connecting-wires to the receiving-instrument, and the vibrations of the sending-disc are reproduced by the disc in the receiving-instrument. The vibrations of the receiving-disc are communicated to the air in the inclosing-case, and this air-chamber being in communication

F. H. BROWN

MAGNETO ELECTRIC TELEGRAPHY.

No. 324,746. Patented Aug. 18, 1885



with the external air the air in said chamber acts as a resonator, and conveys clearly to the ear of the receiving-operator the signals made by the sending-instrument.

I do not desire to limit myself to the precise construction hereinbefore described, as it is evident that many modifications may be made therein without departing from the spirit of my invention.

By placing an inclosing-case around the disc at each end of the line, and by providing these inclosing-cases with suitable mouth-pieces, the instruments are adapted for the transmission of articulate sounds.

In fig. 2 I have shown the receiving-instrument with only one helix on its magnet, which is all that is necessary if the instrument is to be used merely as a receiving-instrument; but if it is adapted for use both as a sending and receiving-instrument or as a sending-instrument, its magnet will be provided with two coils.

Having thus described my invention, I claim—

1. The combination of a permanent magnet having a coil or coils, an armature or disc connected to one pole thereof and free to vibrate over the opposite pole, and a key for vibrating the armature or disc, substantially as described.

2. The combination of a permanent magnet having a coil or coils, an armature or disc connected to one pole thereof and free to vibrate over the opposite pole, a key for vibrating the armature or disc, and stops for limiting the play of the key, substantially as described.

3. The combination of a permanent magnet having a coil or coils, an armature or disc connected to one pole thereof and free to vibrate over the opposite pole, a key for vibrating the armature or disc, and a spring for keeping the key normally out of contact with the disconnected pole, substantially as described.

4. The combination of a permanent magnet having a coil or coils, an armature or disc connected to one pole thereof and free to vibrate over the opposite pole, a key for vibrating the armature or disc, a spring for keeping the key normally out of contact with the disconnected pole, and stops for limiting the play of the key, substantially as described.

5. The combination of the permanent magnets having the coils connected in circuit, an armature or disc connected to one pole of each magnet and free to vibrate over the opposite pole thereof, whereby the vibrations of one of the armatures or discs are transmitted by induced current to the other armature or discs in circuit and reproduced by said other armatures or discs, and an inclosing-case forming an air-chamber around the disc or armature of one or each of the connected magnets, said inclosing-case having a mouth-piece, substantially as described.

6. The combination of the permanent magnets having the coils connected in circuit, an armature or disc connected to one pole of each magnet and free to vibrate over the opposite pole thereof, whereby the vibrations of one of the armatures or discs are transmitted by induced currents to the other armatures or discs in circuit and reproduced by said other armatures or discs, an inclosing-case forming an air-chamber around the disc or armature of one or each of the connected magnets, said case or cases having a mouth-piece, and a key or keys for vibrating the armature or disc of one or each of the magnets in circuit, substantially as described.

In testimony that I claim the foregoing as my own I have hereto affixed my signature in presence of two witnesses.

FRED. H. BROWN.

Witnesses:
C. D. BROWN,
W. A. DARTER.

The following letter, which appeared in the Boston *Transcript*, points out that there is apparently no novel feature whatever in this invention :

BOSTON, Mass, Sept. 17, 1885.

To the Editor of the Transcript: My attention was attracted by an article in the *Transcript* of September 16, page 4, column 7, under the general financial head, entitled, "To Revolutionize Telephoning."

The said article is credited to the Fort Worth *Democrat*, and describes an alleged new departure in the art of telephony, the essence of which is to transmit and reproduce electrically the sounds of the human voice without using batteries of any kind. If we may believe the article in its entirety, this wonderful invention sprang fully armed, Minerva-like, from the brain of Mr. Fred H. Brown, of Texas, and speedily seduced the nice little sum of $1,000,000 from the pockets of a few unsuspecting and guileless New York capitalists.

In an adjacent column a rather sarcastic paragraph alludes to the statement made in London *Truth*, relative to the new penchant of the Americans for boiled water, based upon the doubtful scientific hypothesis that the process of boiling was destructive to the oxygen in the water, which thereby was made more refreshing; and compares that statement with a prior newspaper paragraph cautioning people against drinking aerated liquids because their effervescence was produced by carbonic acid gas.

Yet the display of electrical knowledge in the Fort Worth *Democrat* article is fully as startling, and might with perfect propriety be classed with the boiled water item.

We learn that the transmitter of the new invention is simply a horseshoe magnet, either pole being covered with fine wire coiled carefully; and that the armature is a disc of steel, against which the voice is thrown, to be transmitted through the magnet to the wire; also that the receiver is similar but has a smaller magnet.

Since the telephone was first publicly given to the world by Bell in a paper read before the American Academy of Arts and Sciences, in May, 1876, it has been a common thing for those whose "wish was father to the thought," to deny his inventorship and to ascribe that merit to Reis, Meucci, Cammack, Edison, Gray, Drawbaugh—any one, in fact, to beat Bell. James Watt said that any one making a great invention must pass through three stages in the estimation of the great mass of the public—first, it would be said it was impossible; next, it would be said

Digitized by Google

that he had not done it; finally, it would be asserted that it had long been known.

Mr. Bell has experienced to the full the truth of these observations.

It has, however, rarely been the fate of an inventor to see his invention pass into universal public use, and after the lapse of nine years hear that a new and wonderful achievement of science has been produced, which when described proves to be exactly his own idea. Yet such is the case in the present instance, for the description given of Mr. Brown's new telephone describes exactly the telephone of Mr. Bell before the battery transmitters of Edison and Blake were added.

From its first production in 1876 until some time in 1878, every telephone in use was operated without batteries; and the battery transmitter was a subsequent invention, added to increase its efficiency.

The Bell magneto-telephone was described in the *Transcript* of October 19, 1876.

So far as telephony is concerned, therefore, the wonderful instrument of Mr. Brown is almost a Chinese copy of the original Bell telephone.

It is also, however, implied that this instrument is likewise an innovation in telegraphy. Referring to page 538 of "Electricity and the Electric Telegraph," by Prescott, edition of 1879, we find a description of a complete system of magneto-telegraphy, invented by the well-known German electricians Siemens and Halske, which fully anticipates this feature.

Finally, referring to the United States Patent Office records to ascertain what it is that Mr. Brown really invented, we find that the only patent as yet issued to him is No. 324,746, bearing date of August 18, 1885, and entitled magneto-electric telegraphy; and that an analysis of this patent resolves it into a new form of key combined with the use of a Bell telephone in lieu of an ordinary telegraph sounder.

Such a use was anticipated by the patent of Orazio Lugo, issued December 7, 1880.

As to the financial success of Mr. Brown, it is hardly to be believed that men like Mr. Gould or Mr. Corbin, or that corporations like the Western Union Telegraph Company or the Bell Telephone Company could be beguiled into parting with a million of dollars for an invention which five minutes' conversation with a competent patent attorney would show to be scarcely worth so many mills.

Yours respectfully,

THOMAS D. LOCKWOOD.

THE BROOKLYN UNDERGROUND PROBLEM.

THE following is the full text of the Brooklyn Electrical Subway Commission's report:

BROOKLYN, September 15, 1885.

Hon. Seth Low, Mayor of Brooklyn:

The undersigned, appointed by you as commissioners of electrical subways for the city of Brooklyn, organized as a board on the 9th day of July, and have since held twenty-nine meetings, mostly private, and devoted to the study of the problems presented to the board by the law under which it was created. At a considerable number of public sessions, and also by a voluminous correspondence, the views and proposals of experts and inventors have been examined; and the board has, moreover, made itself acquainted, as far as practicable in so brief a period, with the experience of other cities having electrical subways in this country and in foreign countries. The president of the board has made a personal examination of the various underground conduits and systems in use at Washington, D. C., and has consulted freely with those who, during the past few years, have been conducting experiments with electrical subways in that city. Neither these investigations nor the knowledge previously possessed by the individual members of the board have rendered it possible at this early stage to announce a solution of the problem of underground electrical conductors throughout the city of Brooklyn which shall be thoroughly practicable and at the same time entirely satisfactory and complete. One solution has, indeed, been proposed by eminent authority. The general committee on underground communication, composed of telegraph and telephone managers, the governor of the state and the mayor of the city of New York and others, referred the subject of electrical and mechanical devices to a sub-committee, of which a distinguished electrician, president Henry Morton, of the Stevens Institute of Technology, was chairman, and this sub-committee reported in March, 1884, that nothing would be as good as a properly constructed tunnel of sufficient size to admit the passage of workmen and access to the wires within it; this tunnel to be connected with conduits of sufficient capacity for lateral wires. Another sub-committee of the same general committee reported that there was no law of the state under which a company could construct such a tunnel and conduit system, with the view of leasing the space or the conductors; and it seems to be admitted that no existing company would undertake it for the accommodation of its own wires. That the cost would be very great is evident, and the probability is that it would be greater in Brooklyn than in New York, if the attempt were made to cover with such a system all the area of the city, since the shape of our city of Brooklyn would not permit so easily the distribution of lateral conduits from one main, central tunnel.

So far as the board has been able to learn, no extensive tunnel system has anywhere been constructed for the accommodation of electrical conductors. In London, where the tunnels of the Metropolitan Underground Railway have been utilized, and in Paris, where the large sewers have served the same purpose, these subterranean channels, already existing, could be turned to account without cost, and these cases constitute no precedent applicable to a city where tunnels and suitable large sewers do not exist. Such opportunities, and likewise the opportunities offered by the structures of elevated railways should be utilized, of course, wherever practicable. But it does not follow that nothing more can or should be done until somebody constructs a vast system of tunnels and branches. Even if that were certain to be the ultimate plan (of which this board is by no means assured), tangible relief may be obtained in the meantime from plans less ambitious and comprehensive.

The sub-committee already mentioned examined between May 7, 1883, and March 15, 1884, about six hundred proposed plans and devices. Since the latter date many new ones have been brought forward. Their number, variety and complexity would render the task of this board almost interminable if that task were to be an exhaustive scientific examination of every theory or device submitted to it, coupled with experimental tests of such promising ideas as had not received the seal of successful practice. But this board conceives its duty under the law to be to promote in every possible way relief from the evils which the law was designed to remedy, and it has therefore been from the outset desirous of approving some plan by which a beginning could be made, provided only that such a plan should be reasonably free from mechanical or other objections, and that it should not be of such a nature as to exclude improvements dictated by further experience. The consideration of the subject with a view to immediate practical action has been much simplified by the establishment of certain conclusions, based upon actual conditions in the city of Brooklyn, as well as recognized principles of electrical engineering; and it is to state these conclusions and explain in plain and non-technical language the consequent action of the board that the present report is designed.

1. The purely electrical questions connected with underground electrical conductors are not yet satisfactorily solved. The general experience is that such conductors cost more in the beginning and less for current maintenance than overhead wires; but that they do not last as long. No substance used as an insulator underground has proved invariably and perfectly permanent. The expensive gutta-percha covered wires, employed so widely in Europe, have been deemed (apart from their high cost) the best subterranean conductors; and yet wires of this kind —the same as those used by the British postal telegraph— which had been for years in the underground service of the Western Union Telegraph Company in New York have, within a few weeks past, developed a curious dis-

Digitized by Google

ease of the gutta percha coat which rapidly destroys their insulation. If material so long and so thoroughly known and tested is thus liable to fail, obviously it would not be safe to trust to materials not known or not tested by prolonged experience, no matter how confident their inventors might be of their special virtues. The practical conclusion drawn by this board from the above proposition is that solid conduits—that is, conduits consisting of groups of wires solidly bedded in insulating material (such as asphaltic concrete or the like), should not be extensively adopted in the present state of knowledge and experience. By this it is not meant that experiments might not be cautiously tried with some such method, but such experiments should be limited in extent and prolonged in duration. Only successful operation for some years could overcome the unfavorable presumption created by past experience. In such solid conduits the single conductors have hitherto almost invariably failed, sooner or later, for one reason or another, or for no assignable reason, and when they do fail the whole agglomeration of wires and cement is useless. Repair is impossible and the digging up of the mass to replace it is far more difficult and costly than the original excavation. In Washington, Philadelphia, New York, even in Brooklyn, there are to-day sections of underground conductors laid on this plan and abandoned in despair, but not removed. The immediate problem is thus simplified by excluding for the present solid conduits, and leaving such only as permit the renewal and removal of wires and cables.

2. It is not primarily the duty of this board to solve electrical problems for the benefit of the electrical companies, and in judging of any system of underground connections proposed by such a company the board is concerned with its electrical features only so far as they affect its repairs or changes, and the disturbance of the city streets which those may involve. That is to say, questions of detail concerning insulators, conductors, preventives or remedies for induction, etc., may be safely left to the companies themselves, their interest being to secure and maintain an efficient service in these respects, provided always that the system proposed be one which will permit experiment, repair, renewal and change without excavation. If the streets must be dug up every time an old cable or wire fails or a new one is to be tried, then it is part of the duty of this board to know beforehand what sort of conductors, insulators, etc., will be used in any proposed system, and to approve only that system which promises in these respects the greatest efficiency and permanence. Otherwise, these considerations concern the electricians and business managers of the companies only. The problem is thus further simplified by restricting it for the present to conduits only.

3. Such conduits, unless they were large tunnels, could in all probability not carry the wires for electric arc lights. No discussing of the electrical disturbance produced by currents of high intensity upon neighboring conductors will be undertaken. Nor does the board here pass a scientific judgment upon various suggested remedies. A number of plans have been submitted to the board involving the collection of telegraph, telephone and arc light wires in the same conduit, of small dimensions. In some cases the inventors evidently do not realize the difficulties and dangers involved; in other cases they offer ingenious remedies and protections, not yet tested in practice. But this board is not willing to approve such plans in the present state of electrical science. It is convinced that prudence requires that the electric arc light conductors should be, in the words of the New York sub-committee, already referred to, "widely separated from each other, from all other classes of conductors and from the walls of the conduit." The second of these requirements is the most important, and it simplifies the duty of the board by dividing one problem into two, which can be separately solved. A large tunnel being deemed at present impracticable, the low tension (telegraph, telephone, etc.), conductors and the high tension conductors must be provided for in different conduits.

4. Approaching now the subject of underground conductors for telegraph and telephone service, the board finds that the most important and in some respects the most difficult part of the problem in the city of Brooklyn is presented by the telephone service. The New York and New Jersey Telephone Company, operating nearly all the telephones within the city limits, owns over two-thirds of the electric conductors of all kinds strung overhead in Brooklyn, and occupies either alone or in conjunction with the other electrical companies and with the city departments nearly three-fourths of the poles supporting such conductors. This company, in round numbers, has 2,400 subscribers in Brooklyn, 1,900 of whom require special separate wires, the remaining 500 being grouped upon circuits, so that one wire serves several subscribers. In a few large business blocks in the neighborhood of the City Hall subscribers are so numerous and are so likely to be always numerous, in spite of individual changes, that the wires distributed to such buildings may be regarded as permanent, and there is no difficulty in arranging for their distribution from subways, without the use of aerial supports. But over the larger part of the city, particularly among residences, telephone subscribers are sparsely scattered. To require that connection should be made wholly underground with each of these would be certainly to raise the cost of the telephone service to exorbitant figures, and probably to destroy the service altogether, for the earning capacity of a telephone wire is limited to a fixed sum. No amount of business done over the wire within the city limits increases the income of the company. The charge in Brooklyn at the present time, for instance, is, for a residence, $60 per annum, and the subscriber contracts for only twelve months at a time. In the spring and fall large numbers of persons change their residences and have their telephones moved; at all times there are new subscribers coming in and old ones falling out. Changes due to these causes have been known to amount to several hundred in a month, and as the business is extended these changes will become still more numerous. If complete underground connections were insisted upon in all cases, the telephone company would be obliged either to exact from its residence subscribers a heavy initial payment to cover the cost of the first connection, or a long contract of service, or both, or else it would decline to serve such subscribers. In practice, either of the two former alternatives would probably be the same as the last, since, if the company did not decline the subscriber would. In the opinion of this board the resulting limitation of the telephone service in Brooklyn would be a serious injury to the city. That service is one of the last invented agencies of civilization by which this city is rendered a desirable place of residence. The means of easy communication between Brooklyn and New York, or between distant portions of this city and its business and official centres, promotes its territorial extension and the increase of residences in its beautiful outlying wards. If handsome dwellings are no longer confined to the Heights, it is because of such conveniences as the bridge, the surface, elevated and rapid transit railways, and last, but destined not to be least, the growing telephone system. The existence of such a system, therefore, is a benefit to others than its subscribers for the time being, just as the existence of gas and water supply in a given street enhances the value of property on that street, even of houses not yet supplied, or of vacant lots where no houses stand.

Another consideration, however, has impressed itself upon this board. Assuming that it were mechanically and commercially practicable to make all telephone connections completely subterranean, and that the telephone company could satisfactorily adjust the question of cost with its subscribers, the perpetual digging up of the streets

Digitized by Google

and sidewalks of Brooklyn to make and unmake such connections might become a more intolerable nuisance than the aerial wires. If telephone subscribers were so numerous and so distributed that a main conduit were required in every street, this evil would be reduced to a minimum, though it would still exist. If every house contained a permanent subscriber, or if every house owner maintained the telephone service as regularly as the gas or water service the evil would disappear. But such conditions neither exist nor impend. In the present actual condition of the Brooklyn telephone system, a combination of main subways with overhead conductors, for terminal distribution, is the only thing that can reasonably be undertaken.

Such a combination has been in operation for some years in Washington, D. C., where the cables from the main subways are carried at convenient points to poles, whence the single wires are distributed to subscribers. Washington, fortunately for this plan, possesses numerous lanes and alleys in which such poles can be placed and thus be removed from the main thoroughfares. In Brooklyn, for the most part, such lanes are wanting. In permitting such a system here it would be the duty of the board to exercise a constant vigilance in detail, with the determination of abolishing, as fast and as far as possible, all poles whatever, and of securing the location in the least objectionable places of such as seemed temporarily indispensable.

Immediately upon the organization of the board the New York and New Jersey Telephone Company proposed to lay in Washington street a box conduit of creosoted wood, to contain in separate compartments cables of 25, 50 or 100 wires which would be drawn in through manholes located at convenient points, and would terminate at distributing poles. The board declined at that time to commit itself to the approval of this plan, and required of this company, as of all others operating in the city, the preparation of maps and other information necessary for a full investigation of the subject. A map showing the location of every telephone subscriber and wire in the city was prepared by the company and the minor details of its plan, which was subsequently proposed again on a larger scale, were thoroughly discussed between the board and the experts of the company.

As the result of these inquiries and conferences the board has adopted the following resolutions:

Whereas, The New York and New Jersey Telephone Company has submitted to this board a plan of construction for an underground conduit to contain electrical conductors, which plan the said company propose to carry out immediately on the following lines, viz.: On Fulton street, from DeKalb avenue to the City Hall and below the City Hall, either on Fulton street or on Washington street, to points to be hereafter determined by this board, the said conduit to consist of a partitioned box of creosoted timber, and the wires and cables contained therein to be connected for terminal distribution with overhead conductors at such places and to such extent only as this board may permit;

And whereas, The representatives of the Western Union Telegraph Company and the Gold & Stock Telegraph Company have signified their concurrence in the said plan and their willingness to place their conductors along the said routes in the said conduit, and the said New York and New Jersey Telephone Company has agreed to give in the said conduit sufficient accommodation for the said wires, and also for the wires of the police and fire departments of Brooklyn;

And whereas, The said plan of construction appears to this board practicable, and promises to remove from the said streets a large number of the telephone and telegraph wires and poles which now encumber them; therefore,

Resolved, That this board hereby approves the said plan of construction, subject at all times to such modifications as shall from time to time by this board be made, and subject also to the rules and regulations not inconsistent therewith, prescribed or to be prescribed by the municipal authority having control of said streets. Provided that the number, nature, location and extent of all aerial conductors to be connected with the said subway, and of their poles or other supports, shall be determined hereafter by this board, the present general approval of the said plan, in advance of the determination of details, being given by this board in order to permit making of contracts for the materials required.

A few words in further comment on this action will complete what the board deem it advisable to say at this time. The plan thus approved is subject to the continual control of the board; and the approval thus given does not prevent the board from continuing a patient examination of all other suggested plans. Since this conduit, however, will permit the experimental use of any kind of cable which the telephone or telegraph companies may prefer, the choice of such cables has been left by the board, for the present, to the companies, and the latter have already determined to try several varieties. Persons having special conductors or insulators to recommend are, therefore, referred to either of the above named companies. At the same time, this board will be glad to receive at any time from such persons statements concerning proposed conductors, etc., and will arrange for personal hearings whenever they shall seem to the board desirable. But, pending the tests to be made by the companies, the board does not propose to institute practical tests of new conductors. With regard to the conduit itself, the board is satisfied that timber properly creosoted will be sufficiently durable, and this material having been proposed by the companies referred to, the board has not felt called upon to suggest any other and more expensive one. Creosoted wood is said to be injurious to gutta-percha coating brought into contact with it; and it is not unlikely that wires covered with gutta-percha would have to be further protected if used in this conduit. But lead pipe containing insulated wires can be placed in it without fear of injury from creosote or moisture. Such lead cased cable could be, in the opinion of the board, drawn into the conduit through the manholes, even if the latter were placed at greater distances apart than will probably be the case. The position and detailed construction of the manholes, together with other details of the system, will be determined hereafter, with careful reference to the local conditions on each block affected.

The objection to box conduits, that they may give opportunity for the accumulation of explosive mixtures through leakage from the gas pipes, has been duly considered, and the board believes that effective provision can be made for the prevention of such accumulation in this conduit. A conduit of this character has been successfully operated in Brooklyn during the last nine months. It lies in Court street, from the City Hall to Pacific street; it contains in cables 450 telephone wires, of which about 250 are now in service and the remainder are being rapidly brought into connection with aerial distributing conductors. This conduit has so far given no trouble and has not been opened since it was laid. It is intended to open it and carefully inspect its condition, and such an inspection may determine some points of detail in the larger system of the same general character now to be constructed.

In regulating the terminal distribution connected with the proposed conduit, the board will follow no general and invariable rule, but, considering each locality separately, will strive to reduce to a minimum the necessary amount of aerial conductors, and to cause these to be supported wherever practicable otherwise than upon poles in the streets.

ROSSITER W. RAYMOND, } *Commissioners.*
JOHN REYNOLDS,

THE CONSTRUCTION OF LINES FOR ELECTRIC CIRCUITS.

BY THOMAS D. LOCKWOOD.

(Continued from page 338.)

INSIDE CONSTRUCTION.

THERE is perhaps even more chance for a man to show how good or how bad a job he can do, in inside construction, than there is in outside work. In running wires with-

Digitized by Google

in a building it is often necessary to conceal them, and this is a serious temptation for the workman who is either unable or will not take pains, to perform nice work.

If wires are not to be concealed they may be made a really fine looking piece of workmanship, and in general when wire construction looks well, it is well done.

The three principal styles of attaching wires in buildings, are stringing upon porcelain knobs, tacking down with small staples, and running the wires through cleats. Each of these plans has its good points, and each has its partisans.

I have known men who would always work upon some one of these methods only—but the best constructors are those who are not prejudiced either in favor or against any plan, but who will avail themselves of that mode of procedure which seems best adapted to the case in hand.

Under some conditions it will be found best to tack the wires; at other times the preferable way is to use the knobs—in still other circumstances the cleats should be employed; while cases often arise in which a combination of all the foregoing styles may profitably be adopted. Sometimes also, where many wires are to be led from point to point it is economical to use cables.

The size of wires used inside buildings, varies with the character of the currents used. In ordinary telegraph systems No. 16 or No. 14 double covered copper is the proper size and kind; No. 18 being somewhat too small for such purposes.

If there are a number of wires, and the point to which they are to be led is some distance from the entering point, they may either be led along the ceiling, or along the wall as is most convenient; the wall may however be of brick, in which event it is a saving both of time and labor to run them on the ceiling; and under the same conditions cleats would be used. Black walnut cleats are the best, and ought to be about one inch deep, and three-quarters of an inch wide. If there are not more than six wires to be carried, a two-inch screw at each end, will suffice to fasten up the cleat; but if there are more than that number a screw through the middle is also required. A cleat should never be loaded with more than four wires unless it is first provided with a hard-wood base. This base may with propriety be about three times as wide as the cleat itself, and about three-eighths of an inch thick. The cleat may

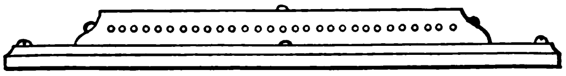

FIGURE 26.

be attached to the base by 1½ inch wood screws, and the base must be screwed to the ceiling by a 1½ inch screw at each corner, and another one about every nine inches, along both sides. Figures 26 and 27 are views representing a based cleat for wires.

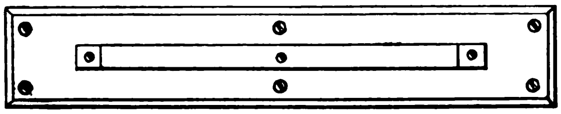

FIGURE 27.

The holes for the wires must be large enough for the size of wire used to pass easily through, and if wire not larger than No. 16 is used, may be as near as three-eighths of an inch from centre to centre. Of course before attempting to screw up the cleats, the position of laths or string pieces should be ascertained, so that each screw may have a bite on solid wood, and not be wasted in the plaster. If more than 24 wires run together, it is more compact and neat to use a cable, which may be fastened to porcelain knobs, or drawn through small brackets with holes about an eighth of an inch larger than the cable itself. To run two wires from point to point there is no better way than to screw porcelain knobs of the kind used in picture hanging, in the wall about an inch and a half below the ceiling or cornice, using two inch round headed screws, and placing them about ten feet apart; when this plan is adopted the "in" wire duly fastened to the incoming line is brought to the top of the first knob, pulled taut, and then given one turn round the knob so as to bring it to the top again; from whence it is passed on to the top of the next knob, and so on from knob to knob, until the last one is reached, when it should be pulled tight and knotted. In like manner the wire connecting with the outgoing line must be run to the lower side of each knob, and given a single turn round each, and it is thus kept parallel to the "in" wire, but about five-eighths of an inch from it, between the knobs. It should be noted that only wire which is well insulated can be run in this fashion, as the wires come together on the knobs; it must also be noted that the wires leaving the last knob must be long enough to be carried wherever desired; and it is always an excellent practice to curl the ends round a pencil, not necessarily for elegance but so that if the wire should break, there would probably still be enough for the requirements. Electric light wires may not of course be fastened in this way. Wires for incandescent lights ought to be run at least two and a half inches apart from one another, and ought to be fixed by porcelain cleats, screwed on to hard-wood base pieces. Wires for arc lights ought to be a minimum distance of eight inches apart, and to be pulled up tight, and fastened in non-conducting supports affixed to the wall. Wires for electric lighting have no business on damp walls, where sooner or later they will give rise to trouble and danger.

Passing through floors, walls, or partitions such wires ought first to be wrapped with unusual care, and then drawn through and surrounded by a tube of some incombustible non-conducting material. Telegraph, telephone or time wires, in fact all wires connected with electro-magnetic systems and instruments, should always be provided with an efficient lightning arrester, placed immediately inside the building, and this should have a stout ground wire, of copper not less than No. 14 gauge. It is hardly necessary to describe that appliance here, as many forms are well-known, are described in text-books, and are on sale at the stores of electrical supply dealers. Telephone wires entering a central station should run first to the lightning arrester, and then to a binding screw or clamp, where they should terminate. Right opposite this terminal should be another, about three inches distant, which in turn is connected with the office wire leading inward; and these wires ought to be connected together by a safety catch or strong current guard which may consist of a thin and narrow strip of tinfoil backed up by being pasted on a card; or a very thin platinum, german silver or lead wire may be used. In New Orleans, at the central telephone office, two wood screws are affixed with a couple of copper burrs at a distance apart of about two inches, and a piece of No. 42 german silver wire is wound round both screws, constituting the safety link—this simple appliance has several times saved the plant from a greater or less destruction due to electric light cross; from this point inward the wires may be led to the switch board by cables.

No central telephone office should in these days of electric illumination fail to be provided with some form of circuit protector—and this device is also equally necessary at the outer ends of cables, and between the instruments and line wire at the subscribers' stations.

The use of wood screws and copper burrs in lieu of binding posts or regular screw connections, is usually regarded as being satisfactory, and being cheap is often preferred. I have found it to work all right, if certain precautions are taken.

The base board upon which the screws are to be inserted must be of thoroughly seasoned wood of medium hardness; if green or unseasoned wood is used for this purpose, it will gradually shrink away from the screws, leaving the wires loose; a washer or burr must also be used between every

Digitized by Google

two wires, and great care must be exercised in entering the screws so that they may not be screwed too deep because if screwed up before the wires are all in place, the screw can never be tightened again, but will turn round in the hole. All screw connections of this kind, and even all binding screw connections, should be frequently tried, to ascertain whether they are tight, and connections which are not accessible, or which are to be covered by other wires should always be permanently made by splicing the wires.

Wires run for currents to work printing telegraphs, should always have heavy insulation such as rubber, kerite, or some like, well-tried non-conductor; paraffined cotton unless very thick being hardly sufficient; such wires may be cleated.

Wires for electric bell work may be insulated with cotton, and No. 18 copper will ordinarily do for this purpose, but if to pass through damp places, or over damp walls, sections of rubber or kerite covered wire must be used.

Where dry wooden walls or partitions are accessible, the wires except for temporary installations may be tacked down, but it is a sign of either recklessness, carelessness or ignorance to place any two wires at any time under the same staples. Heavy risk of short circuiting always attends such a practice which should never be suffered.

In running office wires, where there are several, and where it is requisite that each shall be distinguished from the others, each wire should be insulated by a different colored covering.

It is not within the scope of this series of papers, and indeed it is hardly necessary in view of the numerous text-books referring to the subject, to describe the arrangement of ordinary telegraph instruments; and it seems, therefore, sufficient to say that in establishing a new station or office the main line wires must be united by a cut-out, until the instruments are all in place and connected; that if the operating table is covered by an oilcloth, a space must be cut for the key, to prevent escapes; that both main line wires entering, must be led first to the lightning arrester, then passing through the cut-out, one wire must be continued to the key, and the other to one post of the relay, the other binding screw of the relay being connected by a separate wire to the remaining key screw. The local circuit runs from one pole of the local battery to the register or sounder screw terminal, and from the other pole of the battery to one of the local binding screws of the relay; the circuit is completed by connecting the other relay local screw to the other register or sounder post.

In setting up telephone sets for exchange subscribers, there is really very little to do, beyond screwing up the instruments to the wall, because the inter-connecting wires between the different portions of the apparatus are all run in the shop. There is consequently nothing to do but to connect the in and out, or line and ground wires at the top of the set, connect the battery wires (which are all run) to the battery in the box below, and fasten up the transmitter and receiver in their appointed places. It must be remembered that in either class of installation, the lightning arrester is of no avail, until the ground wire is connected. No time should therefore be lost in attaching it.

(*To be continued.*)

TELEGRAPHING BY CIPHERS.

Last Tuesday the countenance of the operator in charge of a branch office of the Western Union Telegraph Company, located on Broadway, above Canal street, indicated amazement tinctured with disgust as he surveyed a message held at arm's length. The message was written on one of the company's ordinary blanks and read:

To John Chalfant, Tufft's Elephant Corral, Salt Lake City, Utah:
Xabggortza, lzqboptxag, cxmrtzulyo, grmltpaait, lopxxyzabx, racgkpmolb, oozkmrabty, cqmtgdbalm, hiayrtolbc, golzqbagg.

In the corner was written, "Paid $1." That was its unfortunate feature, for it was not the alphabetic jumble of the message that excited the operator's disgust, but a note from the main office pinned to the disguised despatch. The note stated that the operator had been charged $7.30 for the message, and warned him to be careful in future about accepting cipher despatches at a lower rate than that of a full word for each letter.

"I thought ten letters constituted a word, no matter how they were placed; but I'll know better hereafter," sorrowfully remarked the operator, and then added: "The next man that comes in here with a lot of sausage-meat English will hear from me."

The rate to Salt Lake City is $1 for the first ten words, and seven cents per word in excess of that number.

"No, we do not accept ten letters for a word, no matter how they are placed," said an official at the company's main office. "We have had to stop that and charge for the letters in cipher despatches at word rates. This cipher business is troublesome to the operator and makes slow work. Besides that, mistakes are possible. We take cipher messages now at rates as stated, but we do not hold ourselves responsible for their correct transmission."

"How about 'code' words?"

"Any word to be found in Webster's goes at regular rates, whether in a message that reads so that it is understood or otherwise. We only discriminate against the cipher."

"Is much telegraphing done by secret methods?"

"Lots of it. Merchants do it to reduce expenses, and others, from school girls up to the big market manipulators, do a great amount of secret telegraphing."

The use of code systems is greatly on the increase. Some make up their own, but the majority of business men have systems specially printed for them, or make them up out of the cipher books, which are to be had of all commercial stationers.

Mr. E. Parke Coby, the Adjutant of the Veteran Corps of the Forty-seventh Regiment, when asked about cipher systems took the questioner to the fourth story of a printing establishment, where a thin, dark little man, with intensely black eyes, was found cutting three dictionaries to pieces with a huge pair of shears. The dictionaries were in English, Spanish, and German, and the little man cut long strips of words from them, which he pasted on paper, and then drew lead pencil lines from the words to written sentences.

"He is connected with a South American steamship company, and is preparing copy for a cipher system for his line," explained the printer. "We will not print more than half a dozen of the books, but the cost will be over $200. After we strike off the required number of copies we destroy the forms, and do not even keep a sample for ourselves. You see the companies guard their secret ciphers as a man guards the apple of his eye. It would never do to let rivals or interested speculators get hold of their codes, or the company would often be forestalled in the market. We do considerable cipher work for exporters and importers, and men in the iron and foreign trade, as well as for steamship companies, but we never allow the work, when off the press, to be seen by any one except its owners. Cipher systems are coming greatly into vogue with the business men of New York. There is a great saving of expense in the use of the wires and less chance of misinterpretation and mistakes than when sending fully written despatches. Some customers are very secretive about their systems, and others do not appear to care anything for concealment. We get up a cipher system on an interchangeable plan by which not even the printer of the book can know the meaning of the code words."

"What is the expense?"

"Cipher systems, or codes, as they are called, when they are made to order, cost from $50 up. Some run as high as $400, and even more when very extensive. We make a novelty in book form consisting of a system which becomes

Digitized by Google

secretive by the selection of a number. Such are sold at stores, and can be used by anybody."

At the office of Hatch & Foote, the bankers, a small cipher book was exhibited to the reporter. It contained names of stocks, with orders to buy or sell, quantities, advice, &c., all to be represented by a word or two.

"There is nothing secretive about it," said Mr. Emmerson. "We give the books to our customers. It is a saving of money in telegraphing, and an easier and more certain way of communication. We have no need of a secretive system in our general business, though the large operators use private codes."

This was on inquiry found to be the case; but any attempt to get a view of the private codes was regarded as the trick of a stock sharp.

Cashier Quinlan, of the Chemical bank, pointed to a pile of books on his desk, and remarked that they were the cipher systems of various corresponding banks, and that much of the business communicatian between banks is being done by cipher. Banks generally get up a separate system for each bank with which they deal extensively. The cipher books are carefully guarded in the bank's vault, and even then code orders are verified back and forth by other code words, systematized for the purpose, before a transaction involving much money is consummated.

Some houses having foreign connections and the steamship companies use very elaborate and extensive cipher systems. In such systems, over a cipher word column, it may read: "Can you secure —— bundles of hides and find room for the same on the next steamer? If so, telegraph us rates and particulars." At one side of the column of cipher words will be found a column of figures running from one up into the thousands. The figures indicate the number of bundles or quantity, and the entire expression quoted above, together with the number of bundles referred to, may read simply "Bones." If the message "Bones" is sent from New York city to Melbourne, Australia, by the way of the eastern route, it will cost $3, 40 cents being charged per word by the Atlantic cables, and $2.60 per word by the eastern or India lines. Written out in full the original twenty-four words would cost $72.

The Atlantic cables are more liberal in their treatment of ciphers than the land companies. The cables confine a word to ten letters generally, but accept of three cipher letters, whether they make sense or otherwise, for a word. That is, rxy or zbq pass as a single word. Three figures also count as a word; but when figures and letters are mixed, as, for instance, 6 qk or g 5 m, eaeh letter and figure is charged for as a distinct word. This is done to prevent too great a liberty being taken with cable despatches. Nearly all civilized nations, including China and Japan and the nations of South America, permit messages to be sent and received in cipher. Russia and her dependencies are the exceptions. Telegrams to and from Russia, Bosnia, Bulgaria, Servia, Roumania, Montenegro, Herzegovina, and Siberian points must be in open language, that the censors of the wires may read and investigate them at their leisure.

The most expensive all-wire message sent from New York city is one to some of the interior South American towns. They cost by direct cable and by the way of the Eastern $8.20 per word. To go by the coast lines and cables saves considerable on this rate, but when these lines are out of order the message has to take a transatlantic trip. But a message can be sent to distant Bosnia or Servia for only 52 cents per word, 40 cents of which is claimed by the cable companies. To reach Japan costs about $2.70 per word, and China the same amount. Khartoum can be reached at 95 cents, Turkey at $1 via Malta, or 54 cents via France. Messages to the various South American countries run from $1.40 to $3. Siam can be reached for $2.30 per word, and St. Petersburg for 58 cents.

In view of the figures given it will be easily understood why the commercial world takes kindly to cipher systems. —*N. Y. Sun*, Sept. 20.

QUESTIONS AND ANSWERS.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

[70.]—Calibration of Tangent Galvanometer.—"Tangent," of Amoskeag, N. H., inquires for the best method of calibrating a tangent galvanometer, and how to do it. Ans.—One of the best of the several methods is described by Carl Hering in THE ELECTRICIAN AND ELECTRICAL ENGINEER, January, 1885, page 7, as applied to a shunted galvanometer. A silver voltameter is preferable, however, in which case the electro-chemical equivalent of silver should be substituted for that of copper, as given in the formula, and the shunt eliminated altogether.

LITERATURE.

REVIEWS.

Electric B. and O., by J. G. PANGBORN. *Profusely Illustrated.* New York: Baltimore and Ohio Telegraph Co., 1885.

THIS beautiful *brochure* is one of the most elegant specimens of lithography which has been brought to our attention. It has been published for gratuitous circulation among the patrons of the Baltimore and Ohio company. The historical sketch of the Morse system of telegraphy is treated in a popular style, and brings to the attention of the reader the important influence of the Baltimore and Ohio Railroad Company in encouraging the development of this great invention. The introduction is a brief sentiment, penned by President D. H. Bates, in the form of a telegram to the author, "Competitive Telegraphy can be sustained. Electric B. and O. is a success." It is a fac-simile of an actual message in the neat and striking chirography of an "old-time" telegrapher, President Bates himself, and it would add much to the reputation of modern telegraphy if every communication was written by the receiving operator in such unmistakeable characters. The various accompaniments of practical telegraphy are graphically shown by the artist on every page. There is an occasional tinge of fiction grouped with the facts, and the streets of New York will be searched in vain for the original of the messenger who is depicted running at the height of his speed. Perhaps, however, this little work is intended to represent that high standard of perfection in telegraphing which is fondly looked forward to by those who realize its possibilities. It is a novelty in the field of electric literature, and those who secure one by the small investment of a postage stamp, will have reason to commend the excellent taste of its publishers, and the thorough workmanship of the American Bank Note Company, by whom it was designed, engraved, and printed.

CORRESPONDENCE.

NEW YORK AND VICINITY.

Various Underground Notes.—The United States Company Starts Up its 29th Street Station.—The Fire Department Wires.—The Synchronous Multiplex on the Baltimore and Ohio.—The Elevated Railway Motor Experiments.—The United Lines Telegraph Co.

IT is generally supposed that the Commission on Electrical Subways, is obtaining a vast amount of valuable information from "inventors and others" who appear before it for the purpose of airing their schemes. As a matter of fact however, these gentlemen contradict each other to such an extent in their theories, that it is by no means an easy matter for the non-expert to decide between the false and the true. The Metropolitan Telephone and Telegraph Co. has submitted three large maps of its territory, one of which shows existing housetop lines, another the location of telephones in the city, the third, their proposed system of conduits, as well as the pole lines which they propose to retain. The latter form quite a formidable array, and are apparently sufficient in extent to excite the wrath of our metropolitan dailies, who will anxiously inquire why they also are not to go underground.

The United States Illuminating Co. made another unsuccess-

Digitized by Google

ful attempt to obtain permission to transfer the poles and wires from 44th to 29th street, in order to make a connection with their new station at the foot of the latter on the East river. The Commissioner of Public Works made a personal appeal to the individual members of the commission to grant the permit on the ground that it was necessary in order that the company might carry out its lighting contracts with the city. The request was peremptorily refused, whereupon the company substituted business methods for diplomacy, and obtained a right of way over an existing telegraph pole line through 33d street to First avenue, and succeeded in reaching 29th street station with 15 wires. The machinery is now in operation, and death still remains in the air on the east side of the city.

Permission has been granted to the Fire Department to place its wires underground from Fire Hall on Mercer street, to such a distance as will permit them to be carried as a trunk system, at the end of which they will branch out in various directions both underground and overhead. A Broadway circuit will be furnished by the Western Union company in its tube to 23d street. For its own system the fire department will use the Waring cable.

A new building for the fire department is in process of construction at 67th street, to which the central office of the fire alarm telegraph will be removed. It will occupy the upper story, and the additional room secured will permit the introduction of several contemplated improvements in this already superior service. It is not decided as yet whether a duplicate set of apparatus will be constructed, or the present instruments transferred. The original cost of these was $25,000. The number of boxes in the city has nearly reached the limit of signals represented by three figures.

The Baltimore and Ohio Telegraph Co. is making practical tests of the Delany synchronous multiplex system, between this city and Philadelphia. It is working very satisfactorily, yielding six working circuits over one wire, upon each of which business may be transmitted in either direction. The distance between these two cities being comparatively short, and the telegraph business very large, the territory is peculiarly well adapted for the introduction of multiplex apparatus. Additional facilities for electrical communication will also be furnished soon by the American Telephone and Telegraph Co., which is making ready a fine pole line equipped with copper wire, preparatory to the introduction of long distance telephony on an extensive scale.

The Daft motor on the Ninth avenue elevated line made a few experimental trips several days ago, but the conducting rails are again covered with rust, and quiet reigns at present. The Edison people are working away at the Second avenue motor, and if all will exercise patience, the various electrical companies interested in the subject will eventually succeed in eliminating the "bugs" which apparently crop out as the work progresses. The Van de Poele people who have representatives at Elizabeth, N. J., are watching the results of these experiments with considerable interest, in consequence of the success of their motor at Toronto. None of the rival parties exhibit any desire to see their competitors encounter failure believing that such a result would have a dampening effect on the whole business.

The signs of the United Lines Telegraph Co. have been substituted for those of the Bankers and Merchants' at the various offices in the city. There is now every indication of an active competition under the new management, which is apparently being backed by strong parties who enter the contest with the usual enthusiasm.

NEW YORK, September 28, 1885.

CHICAGO.

The Van De Poele Electric Railway at Toronto.—An Experimental Telpherage System at Chicago.—The Ohio Tornadoes.—Selling Lottery Tickets Under an Electrical Alias.—The New Telephone Suit.

FROM Toronto, Canada, comes the most perfect realization up to date of the electric railway principle, and it is a matter of just pride here that the inventor, who is also the constructor, is a Chicago party. A year ago an experimental essay was made upon the same ground, with excellent results; but with that experience Mr. Van De Poele has been enabled to farther perfect his apparatus, until now success is achieved practically, as well as theoretically. The road in question is within the grounds of the exposition at Toronto, and connects with the street car line outside the inclosure. It was at first thought by the street line people that the motor line would be a failure, and with a dog-in-the-manger policy, they refused to lay the needed track inside the grounds. No sooner was there evidence of vitality and commercial value in the electric railway than an injunction was asked to prevent its being run. Fortunately, the line being entirely within the grounds, which were first conceded to the city by the government, and by the city to the exposition managers, there was no authority for granting an injunction on what was shown to be private property.

The entire length of road operated is one mile. The generator is a 40 h.p. dynamo of the Van De Poele pattern, run by a Doty & Son's engine. The wire leading from this to the rail is a No. 4 copper, the other wire being suspended over the track. Connection between this conductor and the motor is made by a deeply grooved pulley which presses perpendicularly upward beneath the wire. At each pole, of which there are 55, the suspension is flexible, so that the pulley readily passes, and by a variable lateral motion in the pulley any inequality in that plane is compensated for.

The motor is a 30 h.p. machine, weighing about 2,000 pounds. The current used varies between 5 and 18 ampères and 1,000 volts.

The grade of the road for about 2,000 feet averages one in twenty, and one or more of the curves, 250 feet radius. Mr. Van De Poele claims that the loss by conversion of power from the engine to the motor is but about 25 per cent., which is far less than half the machine shops in the country lose by their shafting.

The practical part of the story is found in the fact that this little road is doing regular daily work, 14 hours per day, six days in a week, and carrying during the busy portion of the day as high as 250 passengers per trip. On Saturday last, the 12th September, 6,000 tickets were sold, and that number of passengers carried. Of course an average of the passengers per trip for any one day would be no guide, for during the middle of the day there is but little travel, while in the morning the run is all one way, and the rush is in the opposite direction at night. The 6,000 passengers spoken of were carried during the hours between 8 A. M. and 10 P. M., the train making a trip every ten minutes. Owing to the sharp curves and the short track, high speed cannot be maintained.

If there is any other electric railway in the United States to-day which is earning its daily salt, will the promoters please rise and so state?

Mr. Van De Poele has a slightly different arrangement on exhibition here, the carrier being run upon two suspended cables. He has fitted up one of these on a vacant lot between Franklin and Market streets, the connecting wires leading into the back window of the factory. This form of railway is intended for transporting ore and the like along the levels of mines. In the model which traverses a track of about 500 feet, there is a steep artificial grade midway of the track, and it is quite interesting to watch the current measuring instrument as the car climbs the hill, passes the summit and runs down the decline on the farther side, with a scarcely perceptible variation in the rate of speed; yet the current gauge tells when the motor is using less or more power as faithfully as the steam pressure gauge tells its story of energy.

This experimental plant has completely proven, and the practical plant perfectly confirmed Mr. Van De Poele's theory that there is no loss of consequence in not insulating the wires for such purposes, where the current is not of too high potential. The Toronto plant ran equally well in a driving storm that thoroughly soaked everything and everybody exposed, as when all was dry and cold; and save the greater care necessary to keep from accidentally grounding the line by personal contact, and thus receiving unpleasant reminders of the diverted current, all seemed to work as well in one as in the other case.

Those were two very respectable tornadoes which swept through Ohio, on the evening of the 8th September.

That which coursed through the northern portion of the state, commenced as a wind storm near the west coast of Lake Michigan, coursing easterly, changed near Adrian to a tornado, cyclone or what not, and waltzed through sparsely settled districts nearly to Cleveland, where it re-resolved into a stiff blow, and died out. The second, far more destructive to life and property, started on its mission of destruction near the crossing of the Jeffersonville and Ohio and Mississippi railroad in Indiana, also eastward bound, doing its destroying and terrorizing principally near that point, at Cambridge City and Dublin, in Indiana, and the counties of Montgomery, Clark, Greene and Fayette, in Ohio.

The little town of Washington Court House, was nearly cleaned out, the path of the storm lying directly along the principal street of the place.

Capt. A. E. Goodrich, well-known to the general traveling public as the president of the line of lake steamers bearing his name, died on the 14th of September, aged 59 years. In addition to his position as above, Capt. G. was the proprietor and chief promoter of the Bain system of dynamos and lights, both arc and incandescent, and had recently erected a thoroughly comprehensive and complete establishment on the north side for the manufacture of the Bain apparatus. The business of the company will not be seriously disturbed by his demise, however, but continue as before. Capt. Goodrich leaves a son, his only child, about 19 years of age, who is now in Europe with friends from Chicago.

A reporter of one of our daily papers, possessed of more curiosity than credulity, recently investigated a business carried on in an obscure room hardly a fish-line's length from police headquarters. On the window was the legend "The Home Electric Appliance Company—Agents Wanted." Ostensibly for the sale of some magnetic humbug, water for frosting windows, and a fluid ink eraser, the real trade of the concern is selling tickets in the Havana lottery. Presumably the electrical application of

Digitized by Google

the above legend to the lottery business lies in the positive surety of negative results to every one who is struck by that kind of lightning.

Well, the Bell patents are to have another struggle for existence. This time the question is a peculiar one, in that it is claimed that Bell surreptitiously obtained a knowledge of Gray's caveat claims, and changed his own claims to occupy the ground more completely, and so shut Gray out. This, so far, bears on its face an appearance of justice—the premises being granted—that the original inventor should have his just dues. But when we come to the codicil, so to speak, then this matter of injustice between Alexander Graham Bell on the one side and Elisha Gray on the other, is a matter of no consequence whatever. If neither Gray nor Bell invented the telephone, and Reis did, then of what consequence is this secondary clashing of the claims between Gray and Bell?

Frank Geraldy, in a recent article on the Pacinotti and Gramme rings, shows conclusively that the former was in reality the inventor, while the latter by another disposition of the apparatus, and more push and vim became known to the world as the originator of the ring principle in dynamos. The Pacinotti machine was perfect; ring, commutator, brushes, even to its reversibility, and was almost entirely unknown to the world, until the Electrical Exposition of 1881, where it received a diploma of honor. Pacinotti had the idea, and his machine practically expressed that idea; but he stopped at the laboratory model. Gramme, having arrived at the same theoretical point pushed ahead, rendered the machine practical, and gave to it a commercial value. He it was who gave the ring to the world.

To quote from Geraldy:

"For example—it is impossible to approach nearer to the speaking telephone than Reis did in his experiments in 1860; he constructed a telephone which would repeat musical tones, and it is also certain that it repeated some words; nevertheless Reis was not the inventor of the speaking telephone. It is true he produced the phenomena, but without doubt he considered the wonderful result as one of chance, and impossible of practical realization. He did not follow up the results he had obtained with a determination to succeed, conformably to a theory. Bell did—and Bell is the inventor."

Reis's invention had no practical value—and but for some subsequent worker in the field of vibratory law would have lapsed into disuse and oblivion like the phonograph.

The invention of Colt's repeater or revolver is quite popularly believed to be the original of that species of fire-arm. Yet in a chamber of the Tower of London, known as Queen Elizabeth's Armory, on the first floor of the White Tower, may be found the same revolving barrels which made Col. Colt famous, and a nine barreled Celtic revolver which did service in one of the old Irish rebellions, was at one time on exhibition in Buffalo. In both cases the turning of the barrel was accomplished by hand, but although these were known—at least were in existence—they would hardly have been considered by disinterested parties competent to throw the revolver patents, out of which so much money was made, into the public domain. The distance from that old Irish revolver to the first imperfect revolver of Col. Colt, or the Allen "pepper-box," was not nearly so far as that which separates the Reis and the Bell or the Gray telephone.

Somebody always has to eat the drumsticks and wings, and it is usually the fellow who doesn't push his ideas to a finality who gets left in the race; and the ruling is just, that he who gives to the world the advantages arising from his labors, whether mental or physical, is better entitled to protection than he who hides his light under a bushel, and watches for an opportunity to compel a division of profits earned by a more enterprising and industrious laborer in the same field, like the bald (white) headed eagle who never earns a dinner if he can help it, but prefers to rob the fish-hawk of his hard-earned quarry, when hunger presses. There are communists besides those who train round in the wake of brass-bands and red flags on Sunday afternoons.

CHICAGO, September 16, 1885.

BOSTON.

Agitation at the "Hub" over various Telephonic Matters.—Threatened Legislation in regard to Rates.—The Brown Telephone.—The New Time-ball.—Interlocking Signals on the Boston and Albany Railroad.—A Fragment of Morse Telegraphic History.

NEXT to the yacht race between the *Puritan* and *Genesta*, the telephone interests have occupied the minds of the people of Boston and New England quite extensively. First, we have the private lines in a tremor because the telephone company prefer to control the wires, which would seem to be a reasonable idea, as the telephones are not sold, but rented, and the company is blamed if the instruments do not work well; and as a business feature they should control the plant. Next, we have a universal growl because rates are raised. In Salem a dozen doctors agreed to order out their telephones if the rates were raised, and a great many people have come to the same conclusion. This is, of course, the natural protest against further expenditure of money by individuals. But the telephone people have really no other recourse; by next January $10,000,000 of their stock will be *interest* bearing, according to the agreements; money must be raised to satisfy stockholders, and telephones will be used. The telephone people know well that people who have used the telephone cannot get along without it. Threats are made of further legislation this winter; but that is three months in the future, and if the business boom *booms*, every one will feel so good-natured that forgetfulness will rule.

The financial columns of the daily papers have been discussing the present and future status of telephone stocks, particularly of the main company's stock. New England telephone stock at 29 is thought to be as cheap as American Bell at 192, as the latter will not be much of a success ten years hence unless New England is then a good deal more of a success than at present. Although American Bell is earning nearly 24 per cent. at the present time, so say these prophets, including the undivided earnings of its stocks in sub-companies, its present dividends are based upon telephone rentals, which, it is believed by the best telephone thought, must diminish gradually as telephone patents expire, until the treasury rests squarely upon its income from investments.

The statement is made that the American Bell has grown rich at the expense of the sub-companies, and taking in some $20,000,000 of the sub-companies' stock at the same time. To give permanent value to the American Bell the value of telephone exchanges must be increased. In the next five and ten years, it is thought, telephone rentals should go down and the American Bell should grow rich by the enhancement of the value of telephone exchanges. This is the problem now to be worked out. Concessions in telephone rentals are being made by the parent company, and the local companies are increasing their rates in the endeavor to do a profitable business.

The American Bell has enough to think of in defending its patents from the thousand and one assailants, and work out all the questions arising on every hand. Just at present we hear that "Mr. Brown" proposes to revolutionize telephony. This is probably a little one for a cent. [The full details of this instrument will be found on page 377.—EDITOR.]

The new time-ball, which has been greatly missed in our town for some months, will be ready for its daily dropping at the top of the post-office building in a few days.

More than a year ago the city of Boston voted an appropriation to erect a new ball, owing to the enforced removal of the old one from the Equitable building. This appropriation of a few hundred dollars was delivered to the Harvard College authorities having charge of the time service, as they had volunteered to erect the new ball. They delayed, however, until the Navy department instructed Lieutenant Marshall to do the work after the plans of the Naval Observatory, and drop the ball by Washington time. Harvard College is now erecting the ball with the city's appropriation, and will have charge of it, but will use the Naval Observatory's design. Harvard will, however, furnish the time. The new ball will be three feet in diameter, and, as it will be made of steel hoops covered with black canvas, it will be much lighter than the old copper ball. It will drop about twenty-five feet.

The Boston and Albany railroad desires to erect interlocking signals, at its own expense, at Westfield, Mass. The officers of the New Haven and Northampton road, which crosses the B. and A. at this point, at grade, think interlocking signals unnecessary and decline to join in their erection. They will be obliged, therefore, to stop all their trains before crossing, unless they subsequently agree in dividing the expense and using the signals in connection with the Boston and Albany. In the meantime they will be obliged to pay a sum equivalent to the wages of a signalman. A hearing before the railroad commissioners is to be had to settle matters.

I noticed a communication in a daily paper recently, relative to Prof. Morse's underground line, and as a matter of history recite it here. The article was signed by Leavitt Hunt. He says: "When Prof. Morse was engaged in the slow and tedious process of laying his first telegraph wire underground between Washington and Baltimore, a sudden shower compelled him to seek shelter under a bridge. While waiting there, he remarked to his son Charles (who told me of the incident) that 'when it was first proposed to use glass window panes in England it was strongly objected as impracticable on account of the risk of their being smashed. Glass was used,' continued the professor, 'and from here on I mean to string my wire on poles and take the risk.' And henceforth poles were used."

PHILADELPHIA.

Opening of the Novelties Exhibition.—Free Lighting of the Building.—The Western Union to Change its Quarters.—Underground Privileges Granted.—Abandonment of the Fairmount Park Electric Railway.

ALTHOUGH chaos has not wholly abdicated its throne in the big frame building at the corner of Thirty-second and Market streets,

Digitized by Google

the first celestial law is gradually re-asserting its supremacy. The "Novelties Exhibition" is now a fixed fact. The temple of the arts and sciences was formally opened to the public on the 15th instant.

At an early hour artisans and exhibitors were at work, busy as the oft-quoted bee, toiling against time, and trying to condense within a few hours the labors of a week. A very confused scene greeted the eyes of the visitors as their van came trooping in, filling the aisles, crowding the galleries, getting in the workmen's way, getting in each other's way, giving more attention to an empty space and wondering how it was to be filled up, than to the complete exhibit alongside of it, and finally coming to the conclusion that the only sensible way to see the whole show was to take things coolly.

Hon. Wm. D. Kelley was the orator of the day. He spoke of the benefits the institute had conferred upon the public by encouraging inventions, and of the mechanic's debt to it for the opportunities it had afforded him of enlarging his knowledge by studying and comparing his own with the ideas of other men. It had been largely instrumental, he remarked, in preparing the way for the Exposition of 1876, and was an institution that the people should never fail to appreciate and support. Each one of the novelties here displayed, said he, is valuable, inasmuch as it shows the wonderful range of man's inventive genius. Mr. Kelley then announced that the exhibition was open.

One of the features will be the varied illumination of the building. Professor Howe, of Norristown, the inventor of a system of water gas, is having constructed on the grounds an immense wooden tub of the capacity of 15 tons of water. It is part of his plant for making gas. He will supply light and heat to a part of the building and many of the exhibitors. Incandescent and arc electric lights of different companies and Siemens burners are arranged about the place. One electric light firm offered to light the whole building for nothing if all other firms could be excluded, but the offer was declined. As it is, none of those who supply the light and fuel will be paid a cent.

The quarters of the main office of the Western Union Telegraph Company, who occupy the basement and fifth floor of the New York Mutual Life Insurance Company's building at Tenth and Chestnut streets, owing to the constantly increasing business of the corporation, have proven very inadequate, and the managers determined, some time ago, not to renew the lease, which expires on the first of January next, but to secure more commodious quarters in a more central locality. The question of rent, the lease for the present office calling for $12,000 per annum, was another factor in determining the management in making a change of location, and steps were taken to secure either an entire building or quarters large enough to accommodate the business of the company. These efforts have terminated in the leasing for a term of years, from Mr. John F. Betz, the owner, of the old Tabernacle Presbyterian Church building, at the southeast corner of Broad and Merrick streets, at a rent of $7,000 per annum, and the work of improving the structure will be commenced as soon as the plans, which are now being prepared, are completed. It is stated that when the building is ready for occupancy the whole system will be removed to Broad and Merrick streets, and the Tenth and Chestnut streets office will be abandoned. This change will not affect the branch offices at Third and Chestnut streets and at other points throughout the city.

Among the first steps taken since the new location was selected was the introduction in Councils at the last meeting of an ordinance granting permission to the Western Union Telegraph Company to lay its wires underground on Market street, from Twenty-second to Fifteenth, to Chestnut, to Broad, to Merrick, to Front, to Walnut, and river front, and also on Third street, between Spruce and Vine streets. This afternoon a sub-committee of the Electrical Committee of Councils held a meeting for the purpose of considering the matter, and directed the ordinance to be reported with a favorable recommendation, provided the wires on Broad street, from Chestnut to Merrick, be laid underground, inside the curb line, so as not to break the asphalt pavement on Broad street, above Chestnut. Ordinances granting similar privileges to the Bell Telephone Company and the Philadelphia Local Telegraph Company, attached to which was the same proviso regarding Broad street, were also favorably acted on.

The scheme for an electric railway in Fairmount Park has been abandoned because the projectors concluded that with the conditions imposed by the park commission the road would not prove a profitable investment. As at first proposed the road was to run along Belmont avenue, from Elm avenue to Highland avenue, and the builders agreed to light Belmont avenue for the whole distance along their track. The permit was subsequently modified to avoid interference with the numerous drives that cross Belmont avenue, and the route prescribed for the road was from Belmont avenue, just north of the Ohio building, to George's Hill, while Belmont avenue was still to be lighted from Elm to Boundary avenues by the owners of the road. The distance that the road could run was so short, and the expense of lighting Belmont avenue with electric lights, when the track was not laid along it, was so great, that the builders addressed a communication to the park commission relinquishing the right granted them, and the plan has been definitely abandoned. The same gentlemen have arranged to make a trial of their system on the Ridge avenue railway.

PHILADELPHIA, September 19, 1885.

WASHINGTON.

The Underground Work of the Baltimore and Ohio.—The United States Electric Light Co. Putting Down Subterranean Cables.—Absorption of the Thomson-Houston System.—Competition for Lighting the Capitol.—The Western Union Underground Work Still Suspended.—No Indications as to Postal Telegraph Legislation.

UNDER the heavy pressure from the District authorities, another step in the direction of underground wires is being taken. The Baltimore and Ohio Telegraph Co. are now engaged in placing all their wires underground from the depot, where they enter the built up portion of the city, to their main office, Pennsylvania avenue and 14th street. They use the Averell system, by which some 80 or 100 naked copper wires are laid in a trench filled with peculiar asphalt concrete, by which, General Averell claims, each wire is kept from contact with the others or with the earth. By a process of his own he claims to avoid seams by making the work substantially seamless, or in other words, one compact mass, while it is expected to be sufficiently elastic to prevent cracking by the changes of temperature. An experimental section of considerable length was laid two or three years since in the outskirts of the city, where the conditions were such as to give it as nearly a practical test as possible, and it has fully sustained the expectation of the inventor. The insulation remains perfect. The present is therefore to be the first practical use of this system, and if expectations are realized, it will take a front place in the underground system, being economical and offering facilities for laying an unlimited number of wires, the expense per wire diminishing as the whole number of wires increase.

The United States Electric Light Co. is also engaged in laying a series of 12 single wire cables from their new station, near the capitol, to the more western part of the city. They use the Callender insulated cables, laying them in an ordinary pine trough, 12x5, of inch boards, which is thickly coated with tar to prevent its rapid decomposition. This company has secured the Thomson-Houston system, which had been to some extent introduced here, and was likely to prove a formidable rival. They now give their customers their choice of lights. They have rented the station formerly occupied by the Brush-Swan company, which, after expending some $23,000 in plant and experiments, suspended operations.

The United States company is now putting in new boilers, engines, dynamos, etc., and expect soon to be able to meet every demand for lights. In my next I hope to be able to give a full description of their additions to their original plant.

The lighting of the capitol building by electricity is likely to be the objective point with several of the different systems the coming winter. The pressure will be so strong that Congress will doubtless yield to some of them unless they succeed in killing off one another. The fearful defacement of the exterior of the building by the insects attracted in myriads by the powerful lights exhibited by the Brush-Swan company a year ago, has estopped any such brilliant illumination of the outside and surrounding grounds in the future

The injunction suit against the Western Union Telegraph Co., to restrain them from erecting an air line at the terminal of their proposed cable, is still in the courts, and the proverbial law's delay is likely to defer for a long time the result of the experiment with their pump-log conduit.

The present administration, so far as I can learn, has no defined views upon the subject of a postal telegraph. The subject may be mentioned as one of the matters worthy of the consideration of Congress in President Cleveland's annual message, but it is not likely to be urged upon that body.

WASHINGTON, D. C., Sept. 24, 1885.

ELECTRICAL NEWS AND NOTES.

THE NATIONAL TELEPHONE EXCHANGE ASSOCIATION.

SEVENTH ANNUAL MEETING.

Notwithstanding the predictions by many, that the 1885 meeting would not be of much importance, it was fully attended, and the legislation was of a character that evinced a determination on the part of the members to continue the useful work of the association

The meeting was called to order by President Morris F. Tyler at the Narragansett House, Providence, R. I., at 11 A. M., September 8th. Before proceeding to the transaction of business, the president introduced ex-Governor Henry Howard, president of the Providence Telephone Company, who cordially welcomed the delegates with a brief and appropriate address.

Digitized by Google

He commenced by saying that, in behalf of the Providence Telephone Company, and voicing the sentiment of the community, he was sure, he extended a sincere and cordial welcome to the city and state. Remembering the character of the convention which was made up at Cincinnati two years ago, and recalling the impression made upon his mind as to the importance of the interests represented by you, and the intelligence displayed by those who were prominent in the convention at that time, he felt he ought to say more than a word of welcome. "I am not only glad to see you, but I feel," said the speaker, "that we owe you a debt of gratitude for taking note of our little state and accepting the invitation formally tendered to you by myself, and honoring us with your presence to-day. Words of welcome are oftimes a mere form, and I can hardly express how deeply I feel in greeting you. You represent a great and growing interest, and I am sure the entire community will be benefited by your discussions. While I cannot extend to you the freedom of the city, yet I know that you will be welcomed by the citizens at their homes and workshops. I hope you will carry away pleasurable recollections of the city. The Providence Telephone Company desire to extend to you the hospitalities of an excursion down what we are in the habit of calling our beautiful bay. We have arranged that the steamer Philadelphia shall be at your disposal at 1 P. M. Thursday next, for a sail of four hours, returning at 5 P. M. We hope that you will make your arrangements so as to omit your business on that day." The speaker hoped that the occasion would be agreeable, and that the members would have a safe return to their homes. [Applause.]

President Tyler briefly replied, saying that, as chairman of the convention, he felt justified in returning thanks to the Providence Telephone Company, through Governor Howard, for the invitation, and its acceptance of the same.

The first business in order was the calling of the roll of membership, active and honorary.

The American Telephone and Telegraph Company, of New York, was admitted to active membership, and the Callender Insulating and Waterproofing Company and Theodore M. Vail were admitted to honorary membership.

The secretary, W. D. Sargent, presented his report, from which it was learned that there were 41 members in active membership and 31 on the honorary list. The report of the treasurer was presented, from which it was found that there was a cash balance of $37.45, and outstanding bills amounting to $620.

The report of the Executive Committee was presented. The time for holding the session was fixed from 10:30 A. M. to 1 P. M., and from 3 to 5 P. M. It was also recommended that the secretary be paid a salary not to exceed $100 per month, and an assessment of $50 per member of the association, in place of $10, for the next year, to meet the necessary expenses.

President Tyler said that it had been decided that the secretary should be paid a salary, and to have a permanent office either in Boston or New York for the collection and distribution of statistics and matters of interest to the association. Action was deferred upon the recommendations until later in the session.

An invitation was read from the American Bell Company to visit Leicester, Mass., on Saturday, to look into the working of the village system in that place.

RETIRING ADDRESS BY PRESIDENT TYLER.

President Tyler said that the next business was the election of officers for next year, and he wished to decline a re-election, at the same time desiring to give a brief review of the history of the association, dating from September, 1880. He gave an interesting account of the first meeting, held at Niagara. "When we met there," said the president, "we were substantially strangers, and all in a state of enthusiastic uncertainty. He did not think any company could put their hands upon their books and say it had made a cent or expected to make a cent. The members were full of hope, but when analyzed it was exceedingly airy. In the spring of 1881 the conditions were different, matters having become crystallized and the opposition of the Western Union Company and Drawbaugh having been substantially withdrawn. In 1881-2 we were the most self-contented convention ever assembled in one room. All had made money and saw an indefinite expansion of business a long way off. In 1883 we were not so enthusiastic, and in 1884, at Philadelphia, were blue. We have been in periods of eager expectancy, in the flush of almost unexpected success, and now find steady, unremitting work, constant anxiety and careful forecast, not only for to-morrow, but for next year's business, as the result of an established concern with large interests to care for. We are burdened with the responsibility of large interests. Looking back over five years, we can point out many mistakes. It is of no use now to say that we made mistakes. It is of no use to say that we were too confident. It may now be seen, however, that the plan upon which the relations between licensee and licensor were established contained elements of weakness. It was the intention to treat everybody alike, when in fact they were not all alike. It had been forgotten that while one section was unlimited in growth, another might reach its limit. Mistakes have been made, but I do not propose any scheme by which they can be avoided. It is often more difficult to get out than to get in. We who are suffering vitally may think that by one stroke of the pen we may be relieved, but there is another side to the question. It is a problem at which both sides must work. One must be relieved without overburdening the other. We have reached the bottom of the curve and are beginning to climb."

In conclusion, he said that "in many respects the telephone business was dependent upon the general business of the country. He had seen what he believed to be an honest and permanent revival—not speculative. It is our business to keep our eyes open and profit by the experiences of the past, so that in a reasonable time we shall find ourselves on that delightful basis on which some licensees find themselves, where we can pay a dividend on all the stock after deducting both expenses and construction."

ELECTION OF OFFICERS.

The election of officers was then proceeded with, and resulted as follows:

President—C. N. Fay, of Chicago.

Vice-President—George F. Durant, of St. Louis.

Secretary—General C. H. Barney, of Jersey City.

Treasurer—H. L. Storke, of New York.

Advisory Committee—W. A. Jackson, of Detroit; B. E. Sunny, of Chicago; Morris F. Tyler, of New Haven.

Executive Committee—C. N. Fay, of Chicago; James Bigler, of Newburg; R. M. Bailey of Williamsport; C. F. Cutler, of New York; Henry Metzger, of Pittsburg.

Vice-President Durant was called to the chair in the absence of president-elect Fay, and made a brief acknowledgment of the honor.

Mr. Sargent then offered a motion that the association meet at St. Louis next year, the time being left to a committee, consisting of Messrs. Carson, Easterbrook and Metzger, to report at the afternoon session.

A STANDARD WIRE GAUGE.

Mr. W. D. Sargent, chairman of the committee on a standard wire gauge, read the following report:

Your committee on wire gauges received replies from the following parties:

1. Clark Insulated Wire Co., Bristol, Pa., favor the English standard gauge, and state that the present uncertainty in gauges is an embarrassment to their business.
2. W. A. Jackson, of Detroit, Mich., is in favor of a standard gauge, but has no preference.
3. C. N. Fay, of Chicago, favors the English gauge because we buy more or less wire in England.
4. Alfred F. Moore, of Philadelphia, favors the American gauge because all manufacturers of insulated wire use it.
5. E. T. Gilliland, of Boston, favors the micrometer screw and diameters in mils, or thousandths of an inch.
6. The Palmer Wire Co. are very much in favor of a standard gauge, but express no preference.
7. The Phosphor-Bronze Smelting Co., of Philadelphia, favor the English standard gauge, except in the finer sizes, and think if no standard is adopted that all gauges should be abandoned and the micrometer screw used to indicate sizes of the decimal part of an inch.
8. The Standard Electrical Works, of Cincinnati, desire to see a standard wire gauge established because they are constantly annoyed by orders for wire, but without specifying the individual gauge. Their preference is the American gauge.
9. Holmes, Booth & Haydens, of New York, are sensible of the importance of a standard gauge, and recommend the adoption of the English gauge, so that there will be a uniformity between the two countries.
10. The American Electrical Works, Providence, R. I., say that they are greatly annoyed in their business by the multiplicity of gauges. They favor the entire abolition of all gauges, and wires to be identified by their diameters in thousandths of an inch. In practice, they find that this plan works well in their particular business, and they claim to have abandoned the use of special gauges in the work of their factory, and their employés know the wire by its diameter in thousandths of an inch better than they know the gauge.
11. The Western Electric Company, of Chicago, believe that the American gauge and the English standard gauge are the only two to be considered. They prefer the English standard gauge, because we can never hope that the English will adopt ours, and it is a matter of considerable importance to have a uniform standard gauge wherever the English language is used.
12. Clark B. Hotchkiss, of New York, suggests either the English gauge or the American gauge, but with a preference for the English, because it is in use both in France and England.
13. D. H. Bates, president of the Baltimore and Ohio Telegraph Co., thinks the Birmingham gauge is the nearest to perfection of existing gauges, but is much interested in any movement looking toward the establishment of a uniform gauge. He thinks the numbers given with a given diameter should bear

Digitized by Google

some definite relation to the measurements in mils, and wishes to know the result of our deliberations.

14. The Callender Insulating Co. believe that it is of the utmost importance that one uniform gauge should be adopted, and that it would be an immense advantage if it could be made international. They recommend the English gauge in preference to all others.

15. Washburn & Moen believe that the decimal or metric system of gauges would be the best to adopt. They were the first concern to use the " V " gauge in the world, and state they have found it convenient and reliable, and by its use have avoided much annoyance. They express no preference for any particular gauge, but believe that any that would be standardized would soon be generally adopted by manufacturers.

The Western Electric Co. supplement their first reply by the following memorandum from their agent in Antwerp: " You may not be aware that there is no ascertainable gauge in use by the English. The brass people, for example, do not know the gauge called 'B. W. G.' in your telegraph catalogue, and the only way to get what you want is to give the sizes in mils. So far, I have heard of no move among the English to adopt a new standard gauge, and until they adopt that I do not see that you are going to gain anything by abandoning the American gauge, which people now understand. The English gauge has been legalized by the Board of Trade, but this amounts to no more in practice than the legalization of the metric system in America. The metal people are all against the new gauge, and say it was made up by a set of people who knew nothing about the thing practically. Perhaps they say this because they were not consulted in the matter."

Mr. Barton, of the Western Electric Co., commenting on this memorandum, says: " The great difficulty about gauges at present is that there are no safe gauges in common use. The convenience of the public is not so much to get any new gauge adopted as to get all the gauges in use, except one, discontinued. The united association might now secure the almost universal adoption of the American gauge, while in my judgment the adoption of the English gauge would result only in adding one more to the number of gauges now in use. I have learned by discussing the matter with general drawers in the United States that they would much prefer to adhere to the American gauge."

Your committee have placed themselves in communication with all the parties interested. While we have no written or official reply from the Western Union Telegraph Co., we are inclined to believe that if this association would favor the adoption of the English gauge, they would coöperate with us.

The replies come from 15 different parties; seven favor the English, and two the American gauge; six have no preference.

The work of investigating the origin and development of the numerous gauges in various countries, analyzing and comparing their merits and discarding all the advantages without making too great a departure from the Birmingham wire gauge, which is the most generally used, is so thoroughly done by a committee of the British Society of Electrical Engineers, that the committee feel that they will honor themselves and gratify their English friends by accepting their conclusions, and recommending the English standard gauge as the one best adapted to the wants of this country, and in lieu of any arguments of their own in favor of this decision, we refer the members of the association to the report of the English Society, published in volume viii. of their proceedings.

Mr. W. H. Preece, a member of this committee, has very kindly furnished your committee with the " Instructions and Orders of the British Board of Trade," legalizing and making this the standard gauge of Great Britain. He also furnished a number of copies of the gauge, which we submit to the inspection of members.

The committee desire to express their thanks to Mr. Preece for his courtesy in furnishing them with all the information on the subject, as far as the British government was concerned.

W. D. Sargent,
D. I. Carson,
T. B. Doolittle.

In order to bring the subject properly before the meeting, a motion was made that the new English standard gauge be adopted.

Mr. C. B. Hotchkiss said that not only had the English government adopted metrical measurement, but that Germany, France and England were now using the improved English gauge.

Mr. Sargent stated that he had endeavored to confer with the Western Union authorities upon the subject. He would favor the improved gauge, which was simply the old Birmingham gauge standardized, and was practically and scientifically as perfect as the American gauge.

Mr. Lockwood expressed himself very strongly in favor of the new English gauge. It was certainly equal in merit to any other, and he concurred in the belief that as it could never be hoped that England would adopt our gauge, it would be best to adopt the English gauge. Any standard was preferable to the present lamentable need of one, or the multiplicity of gauges not generally recognized. He looked forward to the time when customers will order wire not only of a certain diameter in mils, but of a specific resistance and weight per mile.

Mr. Chester Wilson said that a great many efforts had been made to bring into use a uniform gauge, not so much for the sake of endorsing any particular gauge, but in order to secure a recognized standard of some kind.

Mr. Callender suggested that the association confer with the electric light people before adopting a standard.

Mr. Lockwood expressed himself as decidedly opposed to any such action. The electric light people, in their convention at Chicago, and elsewhere, had expressed such thorough indifference to telephone interests, that he had no desire to compliment them to that extent.

The mid-day recess was then taken.

Upon reassembling at 3 P. M., Mr. T. B. Doolittle, a member of the committee on standard wire gauge, addressed the meeting, saying that he differed with the majority of the committee on this subject. He objected to the adoption of the English gauge, for it would add confusion to the present system of gauges. We have a gauge in general use—the Brown and Sharpe—which is employed by all manufacturers of brass and copper wire, a gauge that is understood thoroughly by the trade, and possesses all the features necessary to a first-class wire gauge.

Mr. Doolittle here presented a diagram illustrating the above statements. The Brown and Sharpe gauge is in common use among the manufacturers of copper and brass wire. If we could take that gauge now and extend it to the field of iron wire, every one would understand it, and there would be no confusion. It would require a generation of time before we could successfully get the English standard introduced. In England now it is only in theoretical use. We have a substantial system of gauging wire, and there is no necessity of changing it.

Mr. Hotchkiss, of New York, reiterated what he said in the morning in regard to the adoption of the English standard gauge. The question of the diameter of the wire and the weight of it is what we must arrive at, and the best results can be derived from the gauge in universal use outside of this country.

Mr. Sise, of Montreal, alluded to the fact that the German government used the English gauge exclusively, Germany and England furnishing practically all of the wire in use on the continent, and the only gauge is the English standard gauge.

Mr. Shippy, of New York, said he thought it was not very important what gauge was adopted. He would suggest the adoption of any gauge, so that it be understood by manufacturers.

Mr. Sargent said that the very confusion that had been alluded to arose from the fact that there had been no standard gauge. The largest manufacturers of wire are in England, and they have adopted this gauge, which is an improvement on the Birmingham gauge, which is in the widest use. It is not well to disregard this because we may have a sentimental feeling prompting us to use the other. We want a gauge which shall be universal.

Mr. Doolittle said that what they wanted to do was to avoid confusion. They had been a quarter of a century trying to perfect their system, and now to attempt to introduce another gauge would be to introduce confusion.

Mr. Barton, of Chicago, maintained that the attempt to adopt a single wire gauge for this generation would not meet with much success. The wire gaugers for sheet and brass use the Brown and Sharpe gauge. They are used to it, and it would be a great job to get them to discontinue it. Then, why adopt the English standard? It is only adopted abroad in theory. If there were only two gauges to be decided upon, the best thing would be to adopt the English gauge, which has some advantages over the American gauge. In this country it could never be used. The Brown and Sharpe gauge is largely used already, and will continue for a good many years. By introducing the English gauge we shall only be working for posterity and not for ourselves. If we undertake to introduce a new gauge, I would like to see a movement to concentrate on the Brown and Sharpe gauge. No matter, however, what gauge is introduced, we shall have to fall back on the relation of thousandths of an inch. All of our manufacturers would draw wire according to the thousandths of an inch.

Mr. Lockwood, of Boston, said that no matter what gauge is adopted, it is probable that corporations ordering wire would say in thousandths of an inch what they wanted ; that when the gauge is not specified the old gauge is understood. He had no doubt as to the propriety of endorsing the views of the European countries in this matter.

Mr. Eckert, of New York, said that he did not believe there were six gentlemen present who could tell the difference between the gauges.

The chairman said that he would like to cast the weight of the association in favor of a uniform gauge throughout the world. This uniformity is creeping into commerce as well as in mathematics, and this association ought not to delay action looking towards a uniform standard gauge.

Mr. Durant said that if all associations could be bound by the action of this association, the passage of the resolution would do

Digitized by Google

some good, but he could not see at present that it would amount to much.

Mr. Metzger said that he could not see what good the resolution would accomplish, unless we made a standard by law. What we want is something by which if a dispute arises between the buyer and seller there shall be a regular standard which shall decide the controversy.

Mr. Wilson, of Philadelphia, said that so long as we adopt the American gauge, we have two in the world. We cannot hope to do away with all but the American; but by recognizing the English standard gauge, we are working in the direction of one uniform gauge and not two. If this telephone association adds its strength by this recognition of the English standard, one step will be taken towards the adoption of a universal gauge. He hoped the vote would be strong in favor of the English standard wire gauge, which would be an independent movement towards actual uniformity.

The resolution was then put to the meeting, and passed with only a few dissenting votes.

The resolution was as follows:

Resolved, That the members of this association, so far as they can, will adopt the English standard gauge for their future work.

In accordance with suggestions made by a number of the members, the secretary was instructed to furnish to the members in circular form a complete statement of the new standard gauge, including a statement of weights per mile of iron and copper, and the resistance per mile of each number of gauge; and also notify the electrical societies and manufacturers of the adoption of the standard gauge, and express the hope that they will follow their example.

The next business in order was the consideration of the recommendations in the report of the executive committee, presented at the morning session.

The first recommendation suggested the levy of an assessment of $40 upon the members to meet the expenses of the current year.

The second recommendation was in the nature of an amendment to the constitution, so that the annual dues shall be $50, instead of $10, which was laid over until the next meeting, under the rules.

The third recommendation was to the effect that it was deemed advisable to employ a secretary at a salary not to exceed $100 per month. The recommendation was approved.

The fourth recommendation contemplated an amendment to the constitution, providing that a paid secretary shall be appointed by the newly elected executive committee, rather than by the association as formerly. The matter was laid over under the rules.

Mr. Storke offered an amendment to the by-laws, enlarging the duties of the secretary in the compilation of reports and statistics presented by the several committees, under the direction of the executive committee. The matter was laid over under the rules.

An invitation was read from the Pawtucket Thread Co. to the association to visit the works, and the invitation was accepted with thanks.

At 5 o'clock an adjournment was taken to Wednesday morning at 10.30 o'clock.

WEDNESDAY, SEPTEMBER 9.

The association assembled at 10.30 o'clock, president C. N. Fay in the chair.

Mr. Carson, from the committee on time and place of the next annual meeting, presented a unanimous report recommending that St. Louis be the place, and the first Tuesday in September as the time. The report was adopted.

Mr. Hall, of New York city, gave notice of an amendment to the constitution. He had found that there were 41 active and 31 honorary members, showing that the membership was nearly equally balanced. His amendment contemplated the establishment of regular and associate, the latter not being directly concerned in telephonic occupation. His amendment to article 2, section 1, is to the effect that any honorary member may be elected by a two-thirds vote of all the members present at any one meeting, such election to be by ballot. He also presented a new article, to the effect that any person or corporation actively interested in the objects of the association, may become an associate member by a majority vote of the members present. Section 2 provides that associate members shall have no vote, but shall be entitled to all other privileges of regular members, and be subject to the same dues and assessments.

The amendments were laid on the table for consideration at the next meeting.

Mr. Lockwood proposed the name of George L. Wiley, of New York, for honorary membership, and he was unanimously elected.

LONG DISTANCE TELEPHONING.

The first paper was prepared by Mr. A. S. Hibbard, of the Wisconsin Telephone Co., and was read by ex-secretary W. D. Sargent, of Brooklyn, N. Y. The subject was, "Some Practical Results of Long Distance Telephoning," and gave an interesting statement of the results obtained by prominent companies in this country and abroad. Mr. Hibbard stated that it was thought that in 1877 the first successful long line results were obtained in experimental tests over telegraph lines. In 1874 many short telegraph lines were equipped with telephones as private lines, and as such were used between stations five to fifty miles apart. In 1878 and 1879 the extension of extra territorial lines, or toll lines, was begun, and the "bean pole" and "barn top" lines were constructed, retarding in some instances the development of successful long line systems. To-day the well-known results of six years' work are exhibited in a showing of 1,252 exchanges, 134,847 subscribers, 539,388 exchange connections daily; 25,766 miles of poles in toll line, 35,631 miles of wire; 18,330 toll connections daily. Mr. Hibbard then gave such figures based upon the statements given by several prominent companies, with exchange lines. The rates were generally uniform, the minimum being 25 cents and maximum of 50 cents for use of a wire five minutes or less. The paper considered the toll ticket plan as profitable, and then devoted considerable space to the matter of interrupting noises. The introduction of resistance into the circuit has been found beneficial in suppressing inductive disturbances, but has in a corresponding degree weakened the telephonic effect. Leaky lines have been found less noisy than those well insulated. The most natural and general remedies are a louder transmitter and a less sensitive receiver. It has been proven beyond dispute that the best wire for long lines is that of the smallest diameter and of the lowest resistance. The hard drawn copper wire was perfected and introduced largely, and the best results in long distance telephoning have been obtained over this wire. In conclusion, the essayist stated that the inventive genius of the world is straining every nerve to produce the "far speaker," and no such pressure was ever brought to bear on any one department of business. For the solution of this problem the public looks to the American Bell Telephone Co. and its licensees in the United States. It is with much confidence that he ventured the opinion that the expectation will be satisfactorily and speedily realized. The Chicago company has a main line of 62 miles, and entire plant of 348 miles; the Wisconsin company has a main line plant of 110 miles, and entire plant of 335 miles; the Michigan company has a main line of 100 miles, and entire line of 190 miles; the Bell Telephone Co. has a main line of 85 miles, from Buffalo to Rochester. The limit of distance in practical and profitable working is about 100 miles, although a considerable business is done over 150 to 200 miles of wire.

In the discussion which ensued, and in response to inquiries as to the present limit of long distance telephony, Mr. Cowles, of Buffalo, stated that there was a line of 90 miles between Rochester and Buffalo, over which, at certain times during the day, conversation could be carried on fairly well. At that distance, however, such work does not constitute a good commercial line. They have no lines over 50 or 60 miles in length, which is about the limit of practical work.

Mr. Sise, of Montreal, said that his company had a main line 800 miles in length, and were working about 3,000 miles of trunk lines. They used No. 9 wire. They worked distances of 150 to 200 miles, the wires not being insulated.

Mr. Uline, of Albany, said that a copper wire from that city to Newburg, 100 miles, was perfectly satisfactory, the wire passing through two switchboards.

Mr. J. J. Fowler, of New Orleans, said the Great Southern company had a circuit of 138 miles, No. 14 copper, which was worked through two intervening exchanges, also 115 miles of No. 14 steel wires as feeders. There was also a line of 120 miles of No. 10 wire, working through three cables.

Mr. Sise did not think the cost of maintenance was of so much importance as that of accounts. At present about 25 cents worth of bookkeeping is required for each 25 cent message.

Mr. Fowler had thought it possible that the large expanse of water in his territory under the lines might have a beneficial effect upon their working.

Mr. McCluer, of Richmond, entertained a similar belief. They have a line to Point Pleasant which works well, while another between Richmond and Petersburg can scarcely be used on account of the disturbances arising from induction. The former line runs along the James river, while the other goes across country. Without presenting any theory, he suggested that veins of metalliferous deposits, or bodies of water running parallel with the wires, might furnish a channel for extraneous currents, thus relieving the wires from such influence.

Mr. Lockwood said that for the benefit of the association he was compiling a list of all the remedies which had been proposed for eradicating induction, which he hoped to present at some future meeting.

Col. Keller, of Boston, stated that their limit of long line work was practically 40 to 50 miles, although they had occasionally talked with Portland, a distance of 110 miles.

Mr. Sargent stated that no difficulty was experienced in working a copper wire between Jersey City and Trenton, 65 miles, but there is difficulty in working through the North river cable to New York, and consequently the wire was of no practical use, as there was but little business between Trenton and Jersey City.

EXCHANGE STATISTICS.

B. E. Sunny, of Chicago, presented the annual paper. There are 42 exchanges of over 50,000 population, representing in round numbers 60,000 subscribers. Of that number 27 exchanges represented 40,000 subscribers. From the tabulated statement it is found that the Providence exchange has 2,162 subscribers, an increase of 270 over last year, a ratio of 1 to 48 in proportion to the inhabitants as per the United States census in 1880, 104,857. Brooklyn has the largest increase in subscribers over last year, 508; New York, second, 444; Chicago, third, 404. Ten exchanges reporting this year and last, and having, in 1884, 18,408 subscribers, have 20,408 in 1885, an increase of 2,000, or 11 per cent. Ten exchanges reporting in 1884 and 1885, in 1884 handled 108,631 connections daily, and in 1885, 136,086, an increase of 25 per cent. in one year. New York has increased 15,000 a day; Brooklyn, 5,000, or double that of last year; Cleveland, 6,000, notwithstanding the increase of only three subscribers; and Chicago, 4,000. On the other hand, Philadelphia, with an increase of 111 subscribers, falls off 4,000, and Albany and Denver show a slight falling off. Providence had 12,046 daily connections. Detroit has 10.6 calls daily per subscriber, Cleveland 10, Chicago 8, New York 7. Providence has 5.2, against 5 in 1884. The offices working on the multiple system, eight in number, average 387 connections per operator. The remaining nine, not multiple, average 268 connections per operator. Albany, Cincinnati and Denver are making less connections per operator than a year ago. Detroit leads with 710; Pittsburg second, 526; Baltimore third, 390. Providence has 335. Eight multiple boards average73 subscribers wires per operator. Nine boards, not multiple, 50 wires per operator. Washington has 126, Milwaukee 91, Brooklyn and Detroit 71 wires each, while Providence has 71 wires per operator. The cost of connections has been materially cut down since a year ago. New York shows the fastest time on record in 10 connections on the Law board, being 2:20—as fast time as Boston on the regular board. Cincinnati is at the bottom of the list, with 23 minutes, and Providence is 14 minutes, or 7 minutes slower than last year. The number of trunk lines is increasing rapidly, nine offices having increased from 1,393 to 1,712, or 23 per cent. Providence alone shows a decrease, being 37, or 5 less than in 1884, 1 less than in 1883, and 11 less than in 1882. Fifteen exchanges, representing 31,955 subscribers, have 491 instrument troubles daily. The average use is 12 times daily. Each telephone, it is estimated, is used 780 times before becoming defective, which may be regarded as a good showing. The report suggested a more universal adoption of the galvanometer for the purpose of discovering defects in lines and instruments that are alike hurtful to city and toll line service. The Chicago company found 112 defective wires, and removed 100,111 ohms resistance, or an equivalent to the resistance of 3,128 miles of No. 12 iron wire. The galvanometer easily detected these obstructions.

The paper was received, placed on file, and a vote of thanks tendered to Mr. Sunny.

LEGISLATION.

An interesting and instructive paper on "Legislation" was read by the treasurer, H. L. Storke, in which he reviewed the legislative proceedings with reference to telephonic interests throughout the country, in an able and comprehensive manner.

Mr. Lockwood, of Boston, in commenting upon the paper, spoke of the necessity of concerted action on the part of the association to defend itself from antagonistic and mischievous legislation.

President Fay also referred to the efforts of the enemies of telephone associations to influence legislation. He claimed that it was generally the gratuitous work of persons who had axes to grind, who expect to be bought off or are hopeful of gaining popularity. They are persons who resort to underhanded measures, and fear to meet open and fair argument. President Fay hoped that the members of the association resident in the several states would keep the secretary fully informed of legislative proceedings for mutual profit and protection, and the secretary would circulate such information among the members from time to time. The association should oppose a united front and seek to protect their interests by the most efficient representation at the state capitals.

Mr. W. H. Eckert gave a summary of the underground work which had been accomplished in New York city. The systems introduced by the Metropolitan company are the Brooks, the Western Electric, and the Edison. From the 39th street exchange the Patterson cables were used, of 50 and 100 wires. The longest was 1,939 feet, and the shortest 1,300. These cables contained 868 conductors, of which 629 are in use. They are placed in a wooden conduit, three feet below the surface. At the 21st street exchange the Edison system was used, with from 100 to 700 conductors in each cable, each wire insulated and then bunched together. The pipe was in 30-foot sections, four feet underground, and covered with boards.

At the Spring street exchange the Brooks system had been introduced, comprising two 4-inch pipes, each containing 380 wires. Out of 760 wires, 501 are in use. The longest pipe is 2,448, the shortest 365 feet. They are placed three feet underground, the cable drawn in and the pipes filled with oil.

There are 614 miles of wire in all three systems, and they are working satisfactorily.

Invitations were received and accepted from the Providence Telephone and Brown and Sharpe manufacturing companies to visit their respective establishments.

The meeting then adjourned until 3 o'clock.

Upon resuming business an invitation was received from the Washburn & Moen Manufacturing Co. for the association to visit and inspect the works of the company at Worcester at such hour on Saturday as convenient. The thanks of the association were voted the company.

THE UNDERGROUND PROBLEM.

The first paper of the afternoon was read by Mr. W. R. Patterson, of the Western Electric Co.; subject, "The Underground Problem." The paper was in substance as follows:

There are two classes who do not admit the existence of the "underground problem," namely, the enthusiastic inventors and promoters of "systems" and the average state and city legislator. The two form a mutual admiration society of gentlemen of vast scientific attainments and disinterested philanthropists. One of the former will admit that it used to be a problem over which electricians had labored in vain: the subject was accidentally brought to his attention by a newspaper report of the delay to the firemen caused by a lot of wires. It immediately occurred to him that those wires might be put underground. He lays no claim to any electrical knowledge, but is only a man of marked practical common sense, unhampered by any scientific hair-spliting. Governed only by the practical common sense requirements of the case, he devoted several hours to thinking on the subject, and the problem was solved. Not satisfied with its general solution, he subsequently went through a long course of mental experiment, thoroughly reduced it to paper, and had it patented. It now only awaits your adoption. The promoter of the Universal Electric, Signal, Telegraph, Telephone, Electric Light and Power Transmission, Underground Insulated Cable, and Conduit Construction Co., knows the system can only be an unqualified success. Isn't it patented? If that isn't enough, didn't the attorney tell the inventor that an examiner in the office overheard the commissioner say to the secretary of the interior that there wasn't anything in the earth or the heavens above, or the waters under the earth, that in any way resembled this wonderful invention?

Some rainy day when the base ball game is postponed, the leading newspaper sends its scientific reporter to find out all about the subject. The reporter is a young man just out of a college where he has learned all about the recession of Greek accents; he laughs scornfully at the man who asks him how they make those little telephone wires hollow, and the next day furtively picks up a piece to examine, finds it solid, and thinks he may have been mistaken, after all, and got a piece of telegraph wire! This knowledge, backed by a vivid imagination, and all the information obtainable from the inventor, furnishes the basis of a long local article and of an editorial in which is duly set forth the meanness, heartlessness and want of regard for the rights, property and lives of our citizens on the part of these grinding monopolies. The philanthropic legislator is impressed by all these things. He "don't take no stock in them scientific chaps; they are all in the pay of some big monopoly, and everyday hoss sense is good enough for him." He knows of no obstacle, mental, physical or moral, that money will not overcome, and here is a chance to get at these "grinding monopolies," help the struggling inventor, make business good, and get the vote of that man who is kicking about a telegraph pole in front of his house. So an ordinance is passed requiring all the wires to be placed underground within thirty days, and what is the use for us at this late day to talk about an underground problem?

You, gentlemen, have all read the information furnished by such a reporter, have suffered under such a legislator, and been taught your business by such an inventor. It has been demonstrated to you beyond question that your wires will work better and for a longer distance, and that there can never, under any possibility, be any outlay for repairs or reconstruction in this underground system. If you have not already, it is probable that you soon will meet with a sufficiently enthusiastic promoter who will demonstrate mathematically that the junk value of your old wire and insulators, and the kindling wood value of your poles and fixtures, will pay for an entire and absolutely perfect underground system. Yet in spite of all these demonstrations, and in spite of the assumed power of a city council to regulate not only the laws of trade, but the laws of nature, it is a fact that men who are practically interested in the matter still see difficulties in the way.

These difficulties may be divided into three general classes—scientific, mechanical and financial. One man tells us there are no scientific difficulties in the way of underground telephony, and another tells us they are insuperable, and both are right. If it is only a question of talking across the street, there are none; if it is a question of talking across the ocean or a continent, they

Digitized by Google

are insuperable with our present knowledge. It would be very rash to claim they must always be so, but it will take something besides an act of the legislature, or an ordinance of the city council, to overcome them. The scientific obstacles in the way of unlimited and universal underground telegraphy and telephony are retardation, escape and induction. These difficulties are common to underground wires for all uses, but are especially troublesome in telephone work. It is the subject which has received least attention from inventors of systems, and it seems entirely beyond the comprehension of most people that an underground wire, say from the Harlem river to Jersey City or South Brooklyn, may, in some respects, be an exact counterpart of an aerial line from New York to Buffalo or Pittsburg.

The causes of retardation are well understood, and its laws well defined, both by mathematical reasoning and by actual experiments upon long submarine cables. Every text book of electricity gives formulas for the speed of working cables, and in connection therewith the distance which a cable of any specifications can be worked at a given speed, which is the telephonic way of stating the case. If a telegraph cable will not work at the rate of 40 words per minute, it may be perfectly feasible to work it at a speed of 20, and it is only a question of providing a duplicate cable if the business requires 40 to be sent. But the laws of acoustics fix the number of vibrations per second for any definite sound, so if a cable cannot carry the requisite number, that is an end of the matter. The distance which can be marked is shown to be a function of the resistance of the conductor and its electro-static capacity. In the present state of metallurgical science it is not to be expected that a better conductor than copper can be found. While chemists and others, principally others, can turn out new insulating compounds almost without number, they can all be grouped into a few generic classes, the properties of which are well understood. It is not to be expected that a material of lower inductive capacity than air can be discovered, or an insulator suitable for underground use which even approximates the low capacity of air. We cannot make up the deficiency by increasing the thickness of the insulator indefinitely, because that has comparatively small effect. Besides these theoretical objections there are practical difficulties in handling a large number of wires which necessarily limit the size of each, and finally there is a limit to the last which precludes the use of metal and insulator in unlimited quantities per foot. The other factor, the resistance of a telephone circuit, has been generally, until of late, considered to be of little importance.

* * * * * *

After the mechanical work connected with the manufacture of the wire and its insulation is properly performed, there still remain mechanical difficulties to be overcome in laying the wires so as to secure the utmost possible durability, or even to insure any service at all. None of these mechanical obstacles are insuperable, or offer as much difficulty as the electrical requirements which we have discussed; yet they are not to be neglected, as any want of forethought or care in handling and protecting the wires may destroy the best electrical work. Most of the mechanical difficulties experienced are of such varying character that only a careful study of the conditions existing in each place can overcome them. In general, the system which requires the least possible work to be performed in the street will escape much of the danger of injury. The number of impossible things that happen and the grand aggregate of all the little things that are done to the detriment of the work by an inquisitive crowd, the weather and the total depravity of inanimate matter, would seem incredible to any one who had not experienced them. What is the best method of protecting underground wires from external injury, is as easy to decide as the best way of protecting human life from loss by accident and violence. The ideal protection for underground wires would be a dry, light, roomy and well ventilated subway. Such a one can be constructed with the utmost facility on paper. It would be found in a city built to order under one comprehensive plan, and before it is lived in completely equipped for 100,000 or 1,000,000 inhabitants, as the case might be, with no subsequent additions allowed. But we have to take cities as we find them, which, like Topsy, "have growed." With the existing systems or more generally lack of systems of sewers, water, steam and gas pipes, street railways, and the general plan of streets and alleys such a subway is impractical. We are reduced to two general methods of protection; one is to lay the wires or cables, and fill in around them with a mass of protecting material, as asphalt or cement; the other is to draw the cables into a previously constructed conduit. Neither method is free from disadvantages when compared with the ideal subway, but the conduit plan seems to have less than the other, and to offer some advantages which are a fair return for the additional expense. In the choice of a method of protection all the local conditions are to be considered, and a plan which is successful in one place may be a failure in another.

The third class of objections we see are financial. It needs no argument to show that it will cost a great deal more to put all the wires of an exchange underground than to carry them on poles and house tops. Saying nothing about its theoretical advantages, air is by far the cheapest insulator known. The insuperable part of the financial difficulty is the proposed throwing away of a full equipment of lines which are in working condition, and replacing them by an entirely new and more expensive system. To even overcome the difficulty due to the difference in cost, the exchange must be made gradually—no faster than the existing lines need renewal.

After all this enunciation of the difficulties in the way of underground service, it may seem that we have left no useful field for it. But there is an extensive field open to such service, and we wish only to look at the matter fairly and impartially, recognizing the existence of serious obstacles which cannot be dismissed with a word. We are convinced of the existence of certain limitations which have been enumerated. We are also convinced that within these limitations there are no reasonable doubts of the perfect success of underground service, as far as any electric troubles are concerned; that while no rigid system may suit all places, there are no mechanical difficulties that cannot be solved by attention to the local conditions; and finally there are no financial objections which are more far reaching than the others, or which would be serious if the change were made gradually. In the proper municipal supervision of electric wires there seems to be an exact parallel with supervision over buildings. When a city reaches any considerable size, the general welfare demands the establishment of fire limits within which the use of inflammable building material shall be restricted. But it has never gone to the extent of compelling owners of wooden buildings within these limits to tear down their structures and replace them with fire-proof material; neither has it forbidden the use of wood in subordinate parts of the structures, or wooden palings and gates in residence streets. It does not refuse permission to prolong the life of wooden buildings by keeping them painted, or by stopping leaks in the roof or replacing broken glass. When a great number of wires accumulate in a neighborhood so as to be a nuisance, it is perfectly proper for those who have the welfare of the city in charge to say that the line must not be rebuilt except underground. But what is the difference between ordering the demolition of a line of poles and wires and the demolition of a wooden building because both are liable to endanger adjacent structures in case of fire, and because both are more useful than ornamental?

The idea of putting all the wires in any city underground throughout their whole extent is not worthy any discussion—it is entirely impracticable. But in any large city the number of wires in the neighborhood of the exchange is a nuisance, both to the public and to the company, and there is no objection, scientific, mechanical or economic, to putting them underground for moderate distances, until they begin to diverge and scatter to reach individual subscribers. In some cases it is absolutely necessary to cable the wires in order to handle them, and there is very little difference in the working of any aerial and underground cables—none at all if they are inclosed in metal. It would be advantageous to use a special conductor for trunk lines and long extra territorial circuits. This is about all that can be done with the present apparatus, and with our present knowledge of the methods of overcoming the difficulties in the way. It is all that has been done in any place, and all that any body of lawmakers can compel to be done successfully. It is doubtful if there is a large exchange in the country that would not voluntarily do as much when the present pole lines need rebuilding. The most conclusive experiments that have been made, and the most extensive work that has been done thus far, have not been under compulsion, but voluntarily. It does not seem that at present we have sufficient data to say absolutely just what length of wire can be worked underground. We are sure that the entire system of any large city cannot be put underground for good scientific and financial reasons. We are sure that the entire system of any small exchange cannot, for financial reasons alone. We are sure that a general and extensive local adoption of underground wires would prevent long distance telephoning, except perhaps from office to office. On the other hand, we are sure that when it is required to handle a large number of wires in a small space for a moderate distance, no one need fear any bad results from using underground cables. The only thing we are not sure of is the exact length of a "moderate distance." But it is probable that no trouble would be experienced in any place up to the limit of 100 wire cables—that is, as far from any office as any 100 wires pursue the same route.

In conclusion, to state our creed, we believe in both aerial and underground wires, without bigotry or intolerance towards either, and with due recognition of a suitable and proper field for the use of each. We do not have much faith in the man who says he can put 2,392 wires in a space 2⅞x3¼ inches; neither do we expect a lineman will be a necessary feature of every circus of the future, to show people how they used to climb poles in the old days of telephone wires.

The paper was received with applause.

The paper of the president, Mr. C. N. Fay, which followed Mr. Patterson's paper, discussed much the same question, and some additional suggestions on the subject were presented for the consideration of the convention. Mr. George F. Durant occupied the chair during its reading. The paper, like its predecessor, was

Digitized by Google

listened to with marked interest, and ordered placed on the records.

The papers were discussed in common, Mr. Thomas D. Lockwood, of Boston, presenting the report of the select committee of the British House of Commons on the subject, and W. D. Sargent, of Brooklyn, gave the experience of the companies in that city.

General Thomas Sherwin, auditor of the American Bell Telephone Co., read a paper on "Telephone Accounts," in which he discussed some of the existing methods of keeping the books of the companies, and presented his idea of a practical and efficient scheme. The paper was in the line of the ideas held at headquarters to establish a uniform system of keeping accounts in the various offices, and provoked much discussion and many additional suggestions.

The session was adjourned at 5 o'clock.

THURSDAY, SEPTEMBER 10.

The last paper of the meeting was read by J. J. Carty, of Boston, giving interesting details of the practical operation of the multiple system of switchboards, as operated in the Boston exchange, where it is believed they have attained their highest present development. The paper and its discussion elicited some points regarding the number of calls answered daily by exchange operatives, which appeared incredible to many delegates. Nashville, Tenn., with 2,500 calls, stood at the head, which is perhaps accounted for by the fact that the local company's stock is very generally distributed in the city, and that every employé of telephone subscribers is expected to answer a call instanter in order to facilitate business. The records of various exchanges were referred to, but it was apparently the general belief that 1,000 calls per operative each day was more than should be exacted.

Mr. Lockwood gave a general history of the patent litigation during the past year, and expressed the opinion that the parent company had never stood in a better condition as regards patents than at the present time.

Mr. Metzger invited the association to meet at Pittsburg in 1887, at which time he believes the city will be free from smoke, on account of the general adoption of natural gas for fuel.

At 12:10 P. M. the meeting adjourned *sine die*.

Most of the delegates, with a number of invited guests, accepted the hospitality of the Providence Telephone Co., and embarked at 1 P. M, on the propeller "Philadelphia" for an excursion down Narragansett Bay.

The weather had been raw and disagreeable during the forenoon, but rapidly improved, and the trip was thoroughly enjoyed by all. A bountiful lunch had been provided, and a well-filled punch-bowl placed well forward and exactly in the centre, that the boat might keep an even keel. Notwithstanding all precautions, however, the heel struck a hidden rock and created a momentary sensation on board, some of the passengers in their anxiety seeking the life-preservers, while at least one was actually put on. The boat was put about when opposite Bristol and returned to Providence, reaching the wharf at about 5 o'clock. There was a general expression of satisfaction at the unremitting attention of Messrs. White and Duxbury in anticipating every want of the visitors, and they were heartily seconded in their efforts by many Providence gentlemen on board.

THE MANUFACTURERS' EXHIBITS.

The earlier telephone conventions offered a better field for the exhibition of switchboards, magneto-bells and kindred apparatus, as interest was largely directed toward the improvements introduced in these devices by rival manufacturers. At the present time more attention is being given to the proper construction of lines, and consequently improved wire and cables formed the larger proportion of the electrical goods shown.

The most prominent and important collection of samples was shown by the American Electrical Works, of Providence, and it is a satisfaction to note the steady improvement which has been made in the finish and perfection of the products of this enterprising establishment. Office and annunciator wire, rubber insulated, both plain and lead covered, office and aerial cables, with anti-induction devices, telephone, incandescent lamp and switch cords, taken as a whole, made a very interesting display. The fine copper wire drawn by Mr. Sawyer's process, received general commendation, it being of uniform diameter throughout, while pieces were shown of extraordinary length, one a five mile piece of .005 diameter, another weighing 12 ounces, .003 diameter. Similar pieces were also shown silk covered. None of the gentlemen present were seen to measure these pieces, they being sure that the labels from this factory never tell a lie.

The Western Electric Company exhibited specimens of various conduits in which the Patterson cables were being used, among them the Dorsett of Chicago, and the wooden conduits used by the Chesapeake and Potomac Company in Washington, and the New York and New Jersey Telephone Company in Brooklyn. A village telephone system dispensing with a central office also attracted considerable attention.

The kerite wire and cables of A. G. Day were shown by Mr. Hotchkiss. All of the standard varieties so well known to the electrical community were there, also specimens of heavily armored submarine cable which has been quite generally adopted for use in the vicinity of New York city, for both telegraph and telephone work, by the Western Union, Baltimore and Ohio, Bankers and Merchants', and Postal companies, and the American Telephone and Telegraph Company.

A very fine exhibit of the Waring lead covered wire and cable was shown by the Standard Underground Cable Co. of New York and Pittsburg.

The Washburn and Moen Manufacturing Company, of Worcester, showed that they keep abreast of the times by a handsome coil of hard-drawn copper wire as the most conspicuous object of their attractive display. In giving their attention to copper wire, however, they have by no means neglected the manufacture of iron, which finds a growing market for fencing purposes.

The Bridgeport Brass Company made a fine display of various sizes of copper wire.

The Okonite Company, of New York, besides samples of their insulated wire, which is rapidly growing in favor, exhibited Mr. J. J. C. Smith's underground system, in which armored cables are used with a very complete arrangement for the connection of wires in the joint boxes.

The Clark Insulated Wire Company showed a variety of samples of rubber covered wire, both with and without the fibrous covering. Line wire of copper, iron and steel, with similar insulation, also formed a part of this exhibit.

The Callender Insulating and Waterproofing Company, in addition to numerous samples of wires and cables insulated with bitite, exhibited elaborate plans of their underground system.

The Standard Electrical Works of Cincinnati exhibited samples of their magneto call-bells, and of the Stevens telegraph key.

The following list of delegates and visitors was in attendance:

Angell, Fred. H.—American Electrical Works, Providence, R. I.
Allen, B. A.—Providence.
Brown, J. M. } Special Agents, American Bell Telephone Co., Boston.
Boyd, Robt. S. }
Baker, Hugh C.—Bell Telephone Co. of Canada, Toronto.
Barney, C. H.—Supt. New York and New Jersey Teleph. Co., Jersey City.
Baker, Ellis B.—Gen. Supt. Southern New England Teleph. Co., New Haven.
Bryan, Samuel M.—Chesapeake and Potomac Teleph. Co., Washington. D.C.
Bailey, R. M.—Central Pennsylvania Telephone Co., Williamsport, Pa.
Barton, E. M.—Vice-president Western Electric Co., Chicago.
Beane, John W.—Consulting Electrician, *Electrical Review*, New York.
Bliss, George H.—Bliss Individual Signal Co., Pittsfield, Mass.
Bailey, Henry L.—Telegraphic Time Co., New York.
Bowen, H. A.—Rhode Island Electric Lighting Co., Providence.
Carson, D. I.—General Supt. Southern Bell Teleph. Co., New York.
Cole, W. J.—District Supt. Southern Bell Teleph. Co., New York.
Cranston, Henry C.—Vice-president Providence Telephone Co., Providence.
Cutler, C. F.—President New York and New Jersey Telephone Co., Brooklyn.
Clark, Joel C.—Treasurer New York and New Jersey Teleph. Co., Brooklyn.
Carty, J. J.—New England Telephone and Telegraph Co., Boston.
Cowles, S. H.—General Manager Bell Telephone Co., Buffalo, N. Y.
Cull, W. H.—Hudson River Telephone Co., Albany, N. Y.
Clark, James—Ohio Valley Telephone Co., Louisville, Ky.
Candee, W. L.—Treasurer Okonite Co, New York.
Cherry, E. V.—Vice-president Standard Electrical Works, Cincinnati.
Callender, W. M.—Callender Insul. and Waterproofing Co., E. Newark, N. J.
Crawford, John—Late Chief Engineer International Bell Teleph. Co., Russia.
Carhart, E. M.—Providence, R. I.
Coop, W. L.—Narragansett Machine Co., Providence.
Childs, W. A.—Law Telephone Company, New York.
Dana, R. K.—Agent Washburn & Moen Mfg. Co., New York.
Driver, William R.—Treasurer American Bell Telephone Co., Boston.
Doolittle, T. B.—Special Agent American Bell Telephone Co., Boston.
Duxbury, J. W.—General Manager Providence Telephone Co., Providence.
Durant, Geo. F.—General Manager Bell Telephone Company of Mo., St. Louis.
Darling, J. O.—American Electrical Works, Providence.
Davis Edward—Davis Individual Call System, Cambridge, Mass.
Douglass, C. H.—Providence Electrical Supply Co., Providence.
Eckert, W. H.—General Supt. Metropolitan T. & T. Co., New York.
Easterlin, John D.—Dist. Supt. Southern Bell Teleph. Co., Charleston, S. C.
Eastabrook, W. N.—New York and Pennsylvania T. & T. Co., Elmira, N. Y.
Fay, C. N.—General Manager Chicago Telephone Co., Chicago, Ill.
French, C. Jay—Asst. Genl. Manager American Bell Telephone Co., Boston.
Fowler, J. J.—Genl. Man. Great Southern Teleph. Co., New Orleans.
Frost, H. P.—Genl. Man. South. New England Teleph. Co., New Haven, Ct.
Fenner, H. N.—New England Butt Co., Providence, R. I.
Gilliland, E. T.—Boston, Mass.
Glidden, Charles J.—Lowell, Mass.
Goodyear M. W.—E. S. Greeley & Co., New York.
Hall, Edward J., Jr.—Genl. Man. American Teleph. & Telegraph Co., N. Y.
Howard, Gov. Henry—President Providence Telephone Co., Providence.
Hudson, J. E.—General Manager American Bell Telephone Co., Boston.
Hotchkiss, Clark B.—Day's Kerite Wire and Cable, New York.
Harrington, F. W.—Western Electric Co., New York.
Ivers, Samuel—New Bedford, Mass.
Jepson, J.—Dist. Supt. Southern New England Telephone Co., Norwich, Ct.
Keller, J. N.—New England Telephone and Telegraph Co., Boston, Mass.
Ker, Wm.—General Manager Pennsylvania Telephone Co., Harrisburg, Pa.
Kinsey, Isaac—Standard Electrical Works, Cincinnati, O.
Kinsey, E. A.—Standard Electrical Works, Cincinnati, O.
Lockwood, T. D.—Electrical Dept. American Bell Telephone Co., Boston.
McCluer, C. E.—Dist. Supt. Southern Bell Telephone Co., Richmond, Va.
Morgan, A. O.—Special Agent American Bell Telephone Co., Boston.
Metzger, Henry—Gen. Man. Cent. Dist. and Printing Telegraph Co., Pittsburg.
Mason, Col. Fred. A.—Bridgeport Brass Co., Bridgeport, Ct.
Martin, T. C.—Associate Editor *Electrical World*, New York.
Marsh, J. W.—Standard Underground Cable Co., New York.
Nicholson, C. A.—Utica, N. Y.
Newell, F. A.—Bradford, Penn.
Oram, J. M.—Oram Telephonic Time Co., Boston.
Pendleton, John M.—President Equitable Electric Co., N. Y.
Patterson, W. R.—Western Electric Co., Chicago.
Price, Chas. W.—Associate Editor *Electrical Review*, New York.
Pope, R. W.—Associate Editor ELECTRICIAN AND ELECTRICAL ENGINEER, N. Y.

Wiley, George L.—Standard Underground Cable Co., New York.
Welch, E. Baker—Davis Individual Call System, Cambridge, Mass.
Woodbury, C. J.—Boston, Mass.

THE RHODE ISLAND CLAMBAKE OF 1885.

Although several of the telephone delegates left Providence after the final adjournment of the annual meeting, their number was more than made good by the arrivals on Friday morning, September 11, of electrical gentlemen who gathered from various quarters to participate in the festivities accompanying the seventh annual clambake tendered to the fraternity by Eugene F. Phillips, president of the American Electrical Works.

The gathering was announced to take place upon the grounds of the Vue de L'Eau club on the eastern shore of Narragansett Bay, and the 10 o'clock boat from Providence landed the first installment of Mr. Phillips's guests, who were followed at intervals during the day by delayed delegations, until an assemblage of about 125 were gathered on the grounds. Each guest upon arrival ascertained that by simply registering his name he would receive a very appropriate souvenir of the day in the shape of a light cane braided at the American Electrical Works, the head being formed of a very perfect imitation of the Bell receiving telephone. Suspended from it by a conducting cord was a miniature silvered clam, emblematic of the occasion.

In order to put themselves in proper condition for dinner at 3 o'clock, a large proportion of those present immediately engaged in athletic sports, such as foot-ball, base-ball, archery and clay-pigeon shooting. The weather was simply perfect, and suitable either for out or indoor amusements. Several gentlemen who prided themselves on their blowing capacity, were quietly introduced to an ingenious lung-tester which had been prepared for the occasion by a Providence joker. The victim was led on by a "steerer," who, as he demonstrated the principle of the machine, turned a switch in the rear which left it loaded with a charge of flour. The new comer, in his anxiety to beat the record, retired from the scene thoroughly deluged with a sprinkling of flour, which was belched forth by the sudden blast of air from apertures on either side of the harmless looking machine. We regret to say that some of our shrewdest New Yorkers were inveigled into this trap by the artless clam-diggers of Rhode Island.

The two base-ball nines, which were organized and commanded by J. O. Darling, of the American Electrical Works of Providence, and F. B. Knight, of New York, engaged in a match which resulted in a victory of the Darling side by a score of 42 to 13.

A continuous lunch was on hand for the benefit of those who could not wait until dinner was served. Other wants of the inner man were likewise provided for in the immediate vicinity. The call to dinner at 3 o'clock was promptly responded to, and the neatly laid tables were immediately surrounded by the largest gathering of electrical representatives which has ever convened upon one of these pleasant occasions. Mr. Eugene F. Phillips read letters of regret from governor Wetmore, mayor Doyle and Stephen D. Field, following with the introduction of Ralph W. Pope, to whom, as a former resident of Providence, he had delegated the duty of welcoming his guests. The preliminary formalities being thus disposed of, the attention of the gentlemen present was readily diverted to the abundance of good things which were successively placed before them. The material being of the best, and its manipulation superb, it was the universal verdict that notwithstanding the success of previous "bakes," the last effort surpassed them all. Nothing can be more certain than that Messrs. Phillips and Sawyer, with their able assistants, Angell and Darling, have again added to their laurels by providing one of the most perfect days of entertainment which could possibly be devised. Such occasions are of substantial value in renewing bonds of friendship and establishing general good feeling among the now numerous branches of the business.

The day closed with the return trips of the shore steamers at 5 and 6 o'clock, which carried back to Providence a most thoroughly satisfied band of excursionists, filled with enthusiasm as to the beauties of Narragansett Bay and the thoroughness of the welcome which little Rhody extends to those who visit her classic shores.

The following is a list of the gentlemen present, who figure in a photographic group which was taken on the occasion:

Adams, George W., Boston.
Allen, C. C., Boston.
Allen, B. L., Providence.
Addeman, J. M., Providence.
Angell, F. H., Providence.
Bailey, H. L., New York.
Bunnell, J. H., New York.
Bly, Charles L., Boston.
Boyd, R. S., Boston.
Brooks, Morgan, Boston.
Blodgett, George W., Boston.
Breckenridge, L. W., Providence.
Busnell, F. T. C., Providence.
Bradford, H. C. Providence.
Burdon, L., Providence.
Bair, W. W., Philadelphia.
Bailey, R. M., Williamsport, Pa.
Barker, E. B., New Haven.
Burgess, P. G., Newtonville, Mass.
Barney, C. H., Jersey City.
Candee, W. L., New York.
Carty, J. J., Boston.
Clark, J. H., Boston.
Canfield, F. P., Boston.
Carr, Rufus B., Boston.
Crofut, W. S., Providence.
Carhart, E. M., Providence.
Cranston, H. C., Providence.
Chace, J. H., Providence.
Cull, W. H., Albany, N. Y.
Crawford, John, Russia.
Downs, Loren N., Boston.
Dempster, W. W., Providence.
Darling, Geo. H., Providence.
Duxbury, J. W., Providence.
Davis, Abiel F., Providence.
Douglass, W. W., Providence.
Drake, Jno. I., Providence.
Darling, J. O., Providence.
Doolittle, T. B., Bridgeport.
Daboll, F. G., Springfield.
Edmunds, Henry, London, Eng.
Frary, W. R., New York.
Fahey, P., Boston.
Frenyear, T. C., Boston.
Fisher, W. M., Attleboro.
Fowler, J. J., New Orleans, La.
Frost, Ellis F., Pawtucket.
Goodyear, M. W., New York.
Gilliland, E. T., Boston.
Gardiner, F. H., Providence.
Hotchkiss, Clark B., New York.
Hunter, M. E., New York.
Hall, W. A., Boston.
Hannaford, F. A., Boston.
Howard, Albert, Boston.
Howard, Chas. T., Providence.
Howard, E. H., Providence.
Hurlburt, P. J., Providence.
Hathaway, W. A., Providence.
Joyce, W. H., Providence.
Jepson, J., Norwich, Conn.
Klein, Charles J., New York.
Kempster, James, New York.
Knight, F. B., New York.
Kingston, J. C., Boston.
Ker, Wm., Harrisburg.
Leslie, E. A., New York.
Lytle, F. M., Boston.
Lytle, H. B., Boston.
Lewis, M. S., Boston.
Lillie, N. W., Boston.
Learned, W. B., Boston.
Lincoln, Chas. E., Providence.
Langstaff, H. C., Providence.
Levett, H. H., Philadelphia.
Morse, J. S., New York.
Marsh, J. W., New York.
Martin, T. C., New York.
Miller, Henry J., Boston.
Metcalf, E. W., Boston.
Manson, George T., Boston.
Millard, Geo. W., Providence.
Munro, W. N., Providence.
Mitchell, D. L. Taunton.
Mason, R. D., Pawtucket.
Newell, F. A. Bradford.
Pope, R. W., New York.
Price, Chas. W., New York.
Perkins, C. A., Boston.
Pettengill, H. J., Boston.
Phillips, Eugene F., Providence.
Peterson, C. G. A., Providence.
Pratt, J. W., New Bedford.
Phipps, C. B., Philadelphia.
Parker, M. G., Lowell.
Robertson, G. M., New York.
Robinson, R. T., Providence.
Remington, C. R. Jr., Providence.
Reilly, J. C., Brooklyn, N. Y.
Reise, Frank, Philadelphia.
Royce, Fred. W., Washington.
Stump, C. E., New York.
Seeley, J. A., New York.
Speer, Geo. B., New York.
Sheehan, C. J., Boston.
Smith, W. M., Boston.
Sawyer, W. H., Providence.
Sims, Gardiner, Providence.
Sherman, Henry H., Providence.
Sargent, W. D., Brooklyn, N. Y.
Sherman, W. R., New Bedford.
Sunny, B. E., Chicago.
Shepardson, A. O., Waterbury.
Sylvester, Chas., Fall River.
Stedman, W. H., North Adams.
Shove, Isaac, Pawtucket.
Stone, Geo. N., Cincinnati.
Starkweather, J. U., Barrington, Mass.
Truex, C. R., New York.
Thornberry, H. S., Boston.
Thomas, V. A., Providence.
Thompson, C. S., Brooklyn, N. Y.
Taber, R. S., New Bedford.
Underhill, Jno. B., New York.
Williams, H. M., New York.
Wetmore, J., A., New York.
Wiley, G. L., New York.
Williams, J. J., Boston.
White, A. C., Providence.
Whittier, R. H., Providence.
Wright, A., Providence.
Wagner, W. R., New Bedford.
Willard, W. H., Worcester.
Wyman, J. C., Valley Falls.
Wilson, A. Jr., Baltimore.
Young, A. M., Waterbury.

THE ELECTRICAL SUBWAY COMMISSION.

The New York commissioners met on August 31 at their permanent quarters, No. 23 West 23d street.

An elaborate plan for an underground system was submitted by Thomas Wallace, 150 Broadway, who proposed the construction of a main tunnel from the Battery to 14th street, sufficiently deep to pass under the gas mains and sewers. The tunnel can also be used for the new water supply in addition to the wires.

J. Hollins Bowly, of Jersey City, presented a description of a conduit to be constructed in sections of either iron or wood.

C. D. Shrieves, of the firm of Shrieves & Cook, of Philadelphia, submitted a plan of a terra-cotta conduit.

Dr. Norvin Green, president of the Western Union Telegraph Company, appeared before the commission to explain what had already been accomplished by that company in underground work. His statement was substantially as follows:

We have an underground system in New York. Wires are run underground from the main office, corner Broadway and Dey street, to the Cotton, Produce and Stock Exchanges, also to the ferries at the foot of Cortlandt and Liberty streets. There are 120 wires to the ferries. We also have tubes laid up Broadway to 23d street. We use gutta-percha insulated wires in iron tubes. We find that this system gives the best satisfaction to ourselves and the least annoyance to the public.

We have tried Brooks's insulation. If it should prove a success, it will afford the cheapest system. In this the wires are covered with cotton, and are drawn through iron tubes which are kept full of paraffine oil. The wires work well so long as the

oil remains pure. A great deal of care is required to make this system satisfactory.

The advantage of a tube is that defective wires can be drawn out and replaced, it being important that the streets be not disturbed.

We use 4-inch pipe, beside the pneumatic tubes, which are of brass. Iron tubes in long pieces afford easy means of drawing cables in and out.

We have *some* poles on Broadway, but our most important lines are on 3d and 4th, 6th and 7th avenues. Our branch offices on Broadway can be served from the line to 23d street. We can place 100 wires in each pipe. It depends on the heaviness of the insulation.

The Brooks system is not inexpensive. The insulated wire alone is worth $100 per mile, against $22 per mile for overhead wire, while the wire does not last as long as it does when strung on poles. We have just taken down some wire that had been up thirty years in the country. The insulation does not last as long underground as it does under water. The average duration under water is from eight to ten years. Many new forms of insulation have been presented to us, but nothing which was satisfactory or lasted over a year.

The system used by us is the same as used in England. The Brooks system has been more satisfactory in Chicago than in this city. I do not think telegraph and telephone wires should go in the same ditch if it can be avoided. The telephone people do not wish to have their wires go in with those of the telegraph companies. People tell us that they have good systems, but we have seen none of them. We can go in with the telephone wires if they can stand it, but do not wish to go with the electric light wires. Neither the district, telephone nor fire alarm wires affect ours.

Our quadruplex wires carry pretty heavy currents, and are pretty hot sometimes. We shall this autumn draw in wires up to 23d and perhaps to 42d street, thence through the tunnel. Some of our branch offices at the exchanges can be reached by underground wires.

The telephone company has three times the mileage of wire that we have, although our wires cover a larger area.

The difficulty is to meet the requirements of the law, without impairing the service. Wherever this is done the result is detrimental to the service. The wires used underground are small, and practically add to the length of the line, being of less conductivity. Such wires cannot be worked as fast. The average speed over the ocean cables is but 12 words per minute, while our Morse system averages 30 and the Wheatstone 130. The retardation is not practically perceptible for distances of two or three miles, but the trouble is that if the wires are buried in New York other cities will follow.

Commissioner Hess—How about Germany? Have they not an extensive underground system?

President Green—They are not putting them underground in Germany as much as they were. It is a government service and the public are not so exacting as here. The city service in London is splendid. There is a special wire to each office. Here we have six, eight or ten offices on a wire, and we have 147 offices in the city. Sometimes when they have business they are obliged to wait until they can get in. The service is not as good as it should be. The city service in London is so good that the district telegraph has stood no show.

The various railways come pretty well into London. With the exception of the Paddington railway none of them are over a mile from the post-office, while some terminate not more than 600 feet away. They come in on viaducts of masonry, upon which the wires are strung on little iron poles. The underground work extends from these several stations to the post-office. The Metropolitan Underground Railway also extends all round the city, affording good facilities for wires. There are more wires overhead than underground, however.

Commissioner Moss—Could not your company utilize the elevated railroad structures? In the original plans of Dr. Gilbert he made provision for both gas and telegraph systems.

President Green—Yes, we could use the elevated railway structures, and we have the privilege on the 3d avenue line. It is not, however, feasible to place pneumatic tubes overhead. The question was considered by our engineers, but it was decided that the changes in temperature would render it impossible to keep them in working order. The pneumatic service is destined to become very important. The time between Dey street and 23d street averages about two minutes. Twenty-five or thirty messages may be sent at a time in a box. Letters or small packages may also be sent. The day we started the pneumatic tubes we took 16 operators off the wires, at the same time improving the service.

At the request of the commissioners, president Green stated that he would send up a map of their lines in the city.

Mr. George D. Sutton, of 146 West 10th street, submitted a model of a system, in which a cast-iron conduit is substituted for the existing curbstones. He had no plan of separating the electric light from other wires.

Mr. W. O. Callender submitted plans for burying the wires, he having given especial attention to the electric light service. He did not believe it practicable to place all the systems together.

At the meeting on September 7th, a communication was received from the Department of Public Works, enclosing a list of all permits which had been granted for the use of the streets of the city for electric wires.

Mr. Bentley, of the Bentley-Knight Electric Railway Co. presented plans of a subterranean system, and also gave a verbal description of the cable which they proposed to use which would obviate all disturbances from induction upon telephone wires which might arise from telegraph and electric light wires running parallel to them. It was well known that metallic circuits would avoid this difficulty, but the doubling of the number of wires in use would be a great undertaking. In the Bentley-Knight system, induction is avoided by the adoption of a similar plan, in which however a single conductor of large capacity is introduced in each cable which is utilized as a general return for all the other conductors in the cable. Plans were exhibited of a conduit made of prepared wood, the positive electric light wires being provided for on one side, the negative on the other with the telephone wires occupying the space between them. Mr. Bentley stated that the main feature of the plans presented was the cable, there being various patterns of conduits which could be utilized.

Hon. A. Macdonald, of Pennsylvania, submitted the Averell system, in which bare wires are imbedded in a solid mass of asphaltum and silex.

John B. King, of New York, proposed to utilize the present sewerage system of the city, by digging down and clearing off the surface of the brick structures which are then to be treated with a coat of asphaltum, and an additional shell of brick laid up outside of the sewers, the space between them being utilized for wires, which are to be strung on iron arches and insulated with glass beads covered with bituminized cloth. He was somewhat fearful that his plan would be appropriated without proper regard for the inventor's rights

Mr. Alguber showed a model of a wooden tube formed of tongued and grooved strips, which he claimed could be furnished 50 per cent. cheaper than anything else, while there was no necessity of placing it more than one foot below the surface.

Mr. Theodore Betzel submitted an elaborate plan by which he proposed that conduits should be built through the blocks instead of beneath the streets. The wires are then to be brought up through a manhole located in the centre of each block, thus requiring but one manhole in each.

Gen. Averell gave further details of the system submitted by Senator Macdonald at the previous meeting.

At the meeting on September 14th, President Loew submitted the following resolution which was adopted:

Resolved, That to afford reasonable facilities to inventors and others for the final submission of plans for electrical subways, this commission continue its regular meetings for that purpose till the 15th day of October next instant. and that thereafter this commission proceed to cause to be devised, the plan of electrical subways intended by the law governing this commission.

Superintendent George B. Scott, of the Gold and Stock Telegraph Co. requested permission to run a cable overhead across the pavement to reach the rear of No. 658 5th avenue near 46th street. His application was referred to Commissioner Hess to investigate and report.

General Averell, representing the Averell Insulating Conduit Co., stated that it was not contemplated in any other system to lay down naked wires but such was the plan he proposed. The compound used for insulation is formed from silica and asphalt. He had experimented two years in producing a suitable material for pavements which was a still more difficult problem than this. The proportion of asphalt required is determined by the void in the silica. In a cubic foot, or 1,728 cubic inches of silica, there was about 540 inches void, which is the measure of the asphalt to go in, but as the asphalt shrinks when cold it is also necessary to determine the amount of shrinkage. The material is impervious to water and is laid down at a temperature of 230°. It is a non-conductor of heat as well as of electricity. As an insulator the asphalt is superior to rosin, and the silica to glass. The asphalt is as sensitive as mercury to the changes of temperature, but when combined with sand it simply fills the void and in its shrinkage binds the particles together forming a mass as hard as granite, beyond which point it cannot contract underground. A slab an inch thick may be placed on a red hot iron, and it will be a long time before the heat will pass through it. No acid, alkali or gas will affect it, it being simply imperishable. All conductors must be insulated. Dry air is the best of insulators. The insulation of this material has however never been questioned. By this system 100 wires may be laid down at half the cost of the cheapest yet proposed. The cost of construction being so small and its permanency unquestioned, the cost of maintenance is actually nothing.

Regarding a system for New York city, General Averell said the following systems must be provided for:

1st. Telegraph wires, including private lines.
2d. Telephone wires.
3d. Signal service *i. e.*, district, burglar and fire alarms.

To estimate the entire cost it would be necessary to know the mileage. There were 1,848 telegraph and 101 other wires crossing 14th street on pole lines. He proposed to reach every block in the city with every system. To do this would require about 20 miles of main conduits, 40 miles of branches and about 340 miles of "twigs." They were perfecting a system of manholes which by permitting the use of switches would reduce the mileage, thus lessening the cost and increasing the efficiency.

At the meeting on September 16th, secretary Moss introduced the following resolution which was adopted.

Resolved, That the Commissioners of the Fire Department be respectfully requested to inform this board if they permit any electric light companies to place any of their wires on the poles belonging to the fire department.

The board subsequently adjourned until September 29th, after which it is proposed to hold daily sessions until the 15th day of October.

JUDGE WALLACE'S DECISION IN THE DUPLEX SUIT.

THE WESTERN UNION TELEGRAPH CO. *v.* THE BALTIMORE AND OHIO TELEGRAPH CO.

United States Circuit Court, Southern District of New York.

Decided September 26.

WALLACE, *J.*:

The complainant moves for a preliminary injunction to restrain defendant from infringing the second claim of Reissued Letters Patent 10,035, Div. C., granted to Joseph B. Stearns, assignor to complainant for "duplex telegraph apparatus."

The motion was resisted on the ground that there was no patentable novelty in the alleged invention, and that the reissue is void because it includes that part of the invention which had abandoned to the public by the delay on the part of the patentee in applying for a reissue.

The original patent was granted to Stearns May 14, 1872; it was reissued April 1, 1873 (No. 5344), and was again reissued in divisions A, B, and C, February 7, 1882.

No doubt whatever is entertained that Stearns was the first and original inventor of a very valuable improvement in duplex telegraphy, which obviated a serious practical difficulty in duplex transmission over long lines, caused by the interference of the return charge arising from static induction with the operation of the receiving instrument at the transmitting end. He did this by a new combination of old instrumentalities. He added to the existing duplex telegraph a condenser so placed that it would receive a charge from the battery equivalent to the charge which the line at the same time received, and would discharge that charge around one coil of the relay at the same time the line discharged its charge around the other coil, so that the armature between the two coils would not be moved by the discharge from the line. As is stated in the affidavit of one of the defendant's experts, no one before Stearns had endeavored to obviate the effects of the static induction upon the receiving instrument in duplex telegraphy with the exception of Varley, and the device used by Varley was not a condenser nor was it in any sense the known equivalent of a condenser.

The invention thus made by Stearns was fully and clearly described in the specification of the original patent. The claim of that patent upon one construction may be deemed to have been narrower than the real invention. This, however, would affect only the question of infringement. A new and valuable invention was described and claimed. It is not necessary in considering the first objection to the validity of the patent to inquire into the prior state of the art. The defendant's expert says: "The claim does not appear to cover any more than the patentee had a right to claim in view of the state of the art at that date." This concession renders such an inquiry unnecessary; but the concession is abundantly fortified by the facts as they appear upon this motion.

The real question in the case would seem to be whether the reissue, so far as it affects the claim infringed, is void.

The claim involved is as follows:

2. "The combination in a duplex telegraph substantially as heretofore set forth, of a battery, a main line, and artificial or compensating line, a rheostat in said artificial line, and a condenser having its terminals respectively connected with said artificial lines and the earth."

The claim of the original patent read as follows:

"In telegraph apparatus for double transmission, the combination with the relay at each station of a condenser, for the purpose of neutralizing the effect of the return current due to the static induction of the line, as set forth."

If the case turned solely upon the question whether the claim of the reissue is broader than that of the original, a sufficient doubt would be suggested to require a motion for an injunction to be denied, because a fair doubt is sufficient to defeat such a motion.

The claim of the original may fairly be construed as limited to a combination in which a condenser is employed in connection with the relay at each station upon a duplex telegraph line. Of course a duplex telegraph implies a line with a receiving and transmitting station at each end of it. The drawings of the patent show only one end of such a line, and the specification of the original describes the apparatus in detail, including a condenser, a battery and a branch circuit or compensating line with a rheostat in it, at that end of the line shown in the drawing. It may fairly be assumed that the claim was expressed in the terms used in order to exclude any implication that the invention consisted in employing the condenser at one end of the line or at one station only.

The real invention of Stearns did not require his condenser to be employed in combination with the rest of the apparatus at both ends of the line. If a condenser were used with the apparatus at one station only the static effect of induction would be neutralized at that end of the line only. The combination would be operative and advantageous to this extent; but it would be less so than if it were used in the apparatus at each station. If condensers were placed at both stations in the required combination, signals at both could be more rapidly and perfectly received.

It admits of fair argument whether it would not have been a fair construction of the claim of the original to interpret it as meaning the combination of a condenser with the two relays of the duplex system. It would have been the duty of a court to construe the claim in such a way as to protect the real invention, unless the language of the specification and the claim would preclude such a construction.

The case does not turn solely on this point, however, because within eleven months from the granting of the original patent it was surrendered and a reissue granted which contained this claim: "Claim 2 is an apparatus for double transmission, the combination of a condenser with a branch or compensating circuit, whereby the effect of static induction upon the receiving relay or instrument is counteracted substantially as and for the purpose herein specified." The specification was amended by inserting as follows: "As the apparatus at each terminal station is similar, the diagram represents the apparatus at one station only." In this claim every unnecessary element of the combination is eliminated.

It covers the invention in the broadest form in which it can be stated. Limited as the terms must be by the descriptive matter of the specification, and read in view of the prior state of the art, the claim was not too broad. It does not require a condenser at each station as a constituent. In other respects, as is argued for the defendant, the claim is narrower in terms than that of the original, because it restricts the combination to one in which the condenser is employed with "a branch or compensating circuit." If this claim included as one of its constituents by fair interpretation "a condenser having its terminals respectively connected with said artificial lines and the earth," it was obviously broader than the claim which is now in controversy.

The claim in controversy is not enlarged by reason of an undue enlargement of the descriptive part of the specification of the reissue. Mr. Renwick, an expert for the defendant, in his affidavit says that he agreed with Mr. Palmer (another expert for the defendant) whose affidavit he has read, "that all the additional descriptive matter which describes more fully and completely the operation and uses of the condenser and the structure of the condenser is legitimate and although not necessary does not widen the invention described in the original patent." He goes on to say that the patentee enlarges his general preliminary statement of the character of his invention because in the original patent "he states in substance that the invention consists in placing a condenser in a certain branch circuit" while the reissue "states in substance that the invention consists in producing artificial currents of static charge and of static discharge at the home station and causing the same to occur simultaneously with those from or on the main line, and that therefore the effect of the latter can be practically eliminated." What the patentee does state in his original is this: "This invention is an improvement upon apparatus for transmitting two signals at the same time from opposite ends of the same line wire, its object being to prevent the effect upon the relay at the sending station of the return current due to the static induction of the line; and it consists in the connection with the apparatus of a condenser of any of the well-known forms." In the first reissue the statement is as follows: This invention relates to duplex telegraph apparatus its object being to neutralize the effect of the return current from the line on the relay or receiving instrument when the line is put to work; and to effect this the invention may in general, be stated to consist in the modes of accomplishing this result by establishing in a branch or compensating circuit connected to the circuit of the compensating helix of the relay, during the time that the line is put to work a return current which will neutralize the effect of the return current from the line upon the line-helix of the relay substantially in the manner hereinafter described." Mr. Renwick's criticism upon the preliminary statement of the nature of the invention contained in the second reissue is that no mention is made in it of a condenser and no assertion that the invention is based upon the use of a condenser, although it is stated afterwards that the result may be conveniently effected by the use of a condenser. Obviously this criticism has no force when applied to the claim in controversy because the claim makes the condenser an element of the combination.

A condenser having its terminals respectively connected with the artificial or compensating line of the combination is precisely what is described in the claim of the first reissue as a condenser,

Digitized by Google

"with a branch or compensating circuit ....substantially as and for the purpose herein specified." The only distinction between the two things which is emphasized in the argument of counsel is that it substitutes "an artificial line" in place of a "branch circuit" or compensating circuit. It is entirely clear that these terms are used synonymously in the electrical art. The compensating circuit is commonly termed the artificial line. The specification states that the branch circuit "is technically called the artificial line in order to distinguish it from the main line." There is no merit in the criticism.

It thus appears that the claim of the second reissue now in controversy is not only no broader than claim 2 of the first reissue, but it is specifically narrower in terms although not so in effect when the specific elements required by construction to be incorporated were read into that claim and it also appears that the second claim of the first reissue was no broader than was warranted by the invention.

The claim in controversy is good notwithstanding other claims of the reissue expand the claim of the original patent or any claims which the patentee might have lawfully made. As to this claim the second reissue is valid if it is invalid as to the other claims, Gage *v.* Herring, 107 U. S., 640.

It protects the complainant if the first reissue was lawful and so much of the invention as was not claimed in the original was not abandoned to the public when that reissue was obtained. There has been no abandonment since the first reissue was granted.

The case then hinges upon the validity of that reissue. Was it a lawful exercise of authority on the part of the commissioner? Was the patentee entitled to reclaim so much of his invention as he had not claimed in the original? The test is found in the rule enunciated in Hahn *v.* Harwood, 112 U. S., 354. That decision covers two propositions applicable here. The first is that a patent cannot be lawfully reissued for the mere purpose of enlarging the claim unless there has been a clear mistake inadvertently committed in the wording of the claim, and the application for reissue is made within a reasonable short time. The second is that the question whether there has been such an inadvertent mistake is, in general, a matter of fact for the commissioner to decide; but whether the application is made in reasonable time is matter of law which the court may determine by comparing the reissued patents with the original, and if necessary with the records in the Patent Office when presented by the records. It was further decided in that case that no invariable rule can be laid down as to, what is a reasonable time within which the patentee must seek for the correction of a claim which he considers too narrow; that it is for the Court to judge in each case and it will exercise proper liberality towards the patentee; but as the law charges him with notice of what his patent contains, he will be held to reasonable diligence. In Coon *v.* Wilson, 113 U. S., 268, the reissue was applied for only a little over three months after the date of the original patent but it was held to be invalid because apparently made to enlarge the scope of the original when the circumstances rebutted any presumption of inadvertence or mistake in the wording of the claim of the original. It appeared that the claims of the reissue were enlarged in order to embrace articles made by the defendant subsequent to the date of the original and not covered by the claim, and it also appeared that what was sought for by the reissue was industriously excluded from the description in the original. This is not such a case.

The claim in the original patent was not one as to which it can be said that the patentee had no ground to suppose it to be narrower than his invention. It did not necessarily and unequivocally confine the patentee to a combination requiring a condenser in connection with the relay at each station. While that might be the interpretation which on first impression would be suggested to the mind of the patentee there was nevertheless room to contend for one which would give him all he was entitled to. Indeed it appears that the Patent Office was of the opinion that the patentee was restricted by the description and drawings to the use of a condenser at one station only. Nothing in the affidavits indicates that the reissue was applied for in view of any new apparatus or patent brought into existence intermediate his application and the date of the original. There was no motive for enlarging the claim which did not exist when he applied for the original patent. The only circumstance that is suggested to show that he did not intend to claim originally what he claimed in his application for a reissue is that shortly before he made his application for the original he had made an application which was withdrawn, which contained a claim as follows: "In a telegraph apparatus for double transmission operated as described a condenser in combination with the relay and resistance coil connected therewith for the purpose of preventing the effect of the return current due to the static charge of the line." In that application the preliminary statement of the nature of the invention and the descriptive parts of the specification differed in many respects from those substituted in the new application. It is apparent on the face of the claim, which makes a resistance coil (or rheostat) an element of the combination, that it was in this respect narrower than the claim in the new application. It was not limited by the words "at each station," but in other respects was a narrower claim. There was nothing in the language of the application to indicate that the patentee supposed his combination would not be operative if the condenser was employed at one station only or that his claim would be too broad unless limited as expressed.

In short there is nothing in the circumstances that he substituted a new application for one previously made to distinguish the transaction from the common one where an inventor is dissatisfied with the contents of his application and wishes to exercise his privilege of preparing and making a new one which shall more carefully and completely protect his rights. There is no fair reason for assuming that he deliberately intended to limit himself in the application which was acted on to a narrower claim than he was entitled to make.

The case is one where the patentee applied for a reissue within eleven months from the date of his original patent in order to correct a claim which might not fully secure his invention and which was certainly so ambiguous as to suggest a doubt whether it was sufficient or not. It is not a case where the suggestion of inadvertence or mistake was a mere prétense of the patentee or one where the mistake was so obvious as to be instantly discernible upon reading the claim. So far from being apparent upon the first inspection of the patent there is room for grave doubt now whether it was not sufficient. The patentee was justified in moving cautiously and saving himself unnecessary expense. The granting of the reissue so far from being an abuse of the power conferred upon the Commissioner was a just and equitable exercise of his authority. The patentee was not guilty of laches; his application was made within a reasonable time; and the reissue, so far at least as it relates to the second claim, was a legitimate and commendable exercise by the Commissioner of the duty devolved upon him by statute.

Although as to the claims in controversy the second reissue must be held valid that reissue in the form of three divisions, containing nine claims in all, was entirely unnecessary. The rights of the complainant were fully protected by the first reissue; the second must have been obtained upon the theory that the patent might be useful as a weapon of offense by means of claims so comprehensive and elastic as to embrace within their scope all subsequent inventions which might be made in the same field of improvement. Intermediate the time of the first reissue and the application for the second reissue, patents for cognate inventions were obtained by Thompson & Selden (September, 1879), by F. E. Jones (March, 1880), and by Gerritt Smith (March, 1881). The reissue in suit was apparently designed to overreach these patents and subordinate them to the complainant's monopoly. The reissue is not to be criticised because the claims of the several divisions cover the invention of Stearns in the broadest form and in the narrowest form in which it is capable of use, but because it is upon its face a flagrant attempt to enlarge the scope of the invention in order that the patent might be more available for the suppression of all competing inventions. It is well calculated to mislead the public into the belief that the complainant enjoys practically the exclusive control of duplex and quadruplex telegraphy as used over long lines. A party seeking the assistance of a court of equity to protect such a patent, appeals to the Court to be astute to discover a legal right which has not been subverted in the unjustifiable attempt to encroach upon the rights of others. A complainant asking the protection of such a patent does not occupy an attitude which is commendable in the view of a court of equity. If the essential motive of those who represented the complainant in obtaining the reissue, was to enable the complainant to assert a colorable title to an invention to which all subsequent inventors must pay tribute, this was an illegitimate and oppressive motive, and the Court should not be eager to come to their assistance when their patent is assailed, by granting them a remedy preliminary to final hearing. As was said by Lord Eldon, in Rundell *vs.* Murray, 4 Jac., 311. "Not only conduct with the party with whom the contest exists, but conduct with others, may influence the Court in the exercise of its equitable jurisdiction by injunction."

This remark was cited with approval by Lord Cottenham in Landers *v.* Smith, 3 My. and Cr. 711,730. The patent as reissued is well calculated to suggest doubts as to its validity, and lead those who examine it to suppose that such an abuse of the statutory privileges cannot be tolerated. The officers of the complainant have only themselves to blame if others had acted on the assumption that the patent cannot stand. The defendant has acted upon this belief. Under such circumstances the complainant should not have the stringent remedy applied for, and it is not only within the fair discretion, but it is the duty of the Court to deny preliminary relief, and leave the complainant to the ordinary relief at final hearing.

IMPORTANT ELECTRIC LIGHT CONSOLIDATION.

The American Electric Manufacturing Co. has secured the control of the Fuller-Wood system of electric lighting with the new five-story factory on West 18th street, which is said to be one of the best and most thoroughly equipped establishments for the

Digitized by Google

manufacture of electric lighting apparatus in the country, the machinery being new and of the most approved pattern. The papers have been executed between president William H. Appleton, of the Fuller-Wood company, and president Edward H. Goff, of the American company, by which the latter company secured possession of the property of the former corporation. Prof. Wood's improvements and latest inventions are said to be of great value, and when put into practical use will supersede all of the old Fuller patents, and make the system a most complete and economical one in cost of construction and operation. The contract which has been signed carries these with it.

The alliance recently made with the Edison company and this action of the American company, by which both corporations labor with one another in introducing their systems, will enable it to compete successfully with any gas or electric company.

In a recent interview, president Goff was questioned as to the action of the American company in abandoning the Thomson-Houston system, which he had labored so long and earnestly to establish. He declared he had nothing against the Thomson-Houston system. He thought it was for the advantage of his company to take hold of the new system. In the first place it was as profitable to operate, and fully as economical to build, as any other system. Next, it would enable the American companies to be independent of all other companies and to derive the entire profits from the manufacture and sale of the apparatus. The New York factory he expected to run to its fullest capacity in the manufacture of dynamo machines, and that the lamps would in all probability be made by the Electrical Development and Manufacturing Co., of Boston. The American company claims to have orders now on hand for over $200,000 worth of new apparatus.

THE EDISON INCANDESCENT SYSTEM.

Incandescent lighting from central stations, is making steady progress as will be learned from the following list of plants established by the Edison company.

Name of City or Town.	State	Capacity of Machinery.	Lamps Suppl'd
Berlin	Germany	14,000	......
Milan	Italy	8,000	......
New York	New York	8,000	1,300
Bellefonte	Pennsylvania	800	1,200
Middletown	Ohio	500	700
Williamsport	Pennsylvania	3,200	4,500
Piqua	Ohio	1,000	1,200
Newburgh	New York	2,400	3,000
Tiffin	Ohio	1,000	1,200
Fall River	Massachusetts	2,400	3,000
Hazleton	Pennsylvania	1,000	1,200
Lawrence	Massachusetts	3,200	4,500
Shamokin	Pennsylvania	2,400	3,000
Brockton	Massachusetts	2,400	3,000
Circleville	Ohio	1,050	1,200
Cumberland	Maryland	1,000	1,200
Des Moines	Iowa	1,600	2,000
Appleton	Wisconsin	500	2,000
Harrisburg	Pennsylvania	4,800	5,000
Westchester	Pennsylvania	1,600	2,000
Johnstown	Pennsylvania	1,000	1,200
Tamaqua	Pennsylvania	1,600	2,000
McKeesport	Pennsylvania	1,600	2,000
New Brunswick	New Jersey	1,600	2,000
Boone	Iowa	600	1,000
Wilmington	Delaware	1,600	2,000
		68,850	51,400

The following classification of isolated plants will be found of special interest, as showing the various lines of business which have found it advisable to adopt private incandescent lighting.

PLANTS ESTABLISHED FOR AND OWNED BY PRIVATE USERS.

	Plants.	*Lamps.*
Educational institutions, public asylums, and hospitals	26	7,173
Hotels, apartment houses, and club rooms	23	11,035
Theatres and places for amusement	20	14,033
Banks, office buildings, stores, residences, &c,	73	23,757
Newspaper and other printing offices	30	6,521
Sugar refineries	11	4,864
Flour mills and grain elevators	26	1,934
Cotton, woolen, and textile fabric mills	81	25,898
Pulp and paper mills	30	3,318
Oil refineries, distilleries, dye houses, chemical works, and meat-packing houses	29	8,392
Water works, rubber factories, and miscellaneous manufacturing establishments	39	5,088
Iron works, car and machine shops	40	7,828
Furniture and pianoforte manufactories and wood-working establishments	15	2,360
Steamships, steamers, yachts, &c.	51	8,092
Grand totals	494	125,293

This makes a grand total of 177,000. Or, if the lamps actually placed in isolated plants were taken instead of merely the dynamo capacity, a grand total of upward of a quarter of a million Edison lamps in actual use in this country alone.

AN INCANDESCENT LAMP FOR LIGHTHOUSES.

A Washington despatch says that Major David Porter Heap, engineer-secretary of the Lighthouse Board, has perfected a new arrangement of the electric light in its application to lighthouses which promises to be of great services in the time of fogs. This discovery of his he proposes to give to the government.

He early saw grave objections to the use of the arc light, the principal one being that it penetrated fog but little more than other and feebler lights now in use. His conclusions in this respect have recently been verified by the experiments at South Foreland, England, made by the Trinity House, where it was shown that a 15,000 c. p. electric light penetrated fog very little further than an oil or gas light of 2,500 c. p. The reason of this is that the arc light is mainly composed of rays towards the violet end of the spectrum, while oil light is composed of rays towards the red end, and these latter rays are the most fog-penetrating.

What is needed most for lighthouse purposes is a very powerful light, rich in red and yellow rays. This latter condition is fulfilled in the incandescent lamp, but unfortunately those so far constructed are of but small candle power, the brightest so far made not much exceeding 150 candles. Major Heap believes that this power can be greatly increased, and as a step to this end has invented and intends to try experimentally a lamp constructed as follows:

The size of the flame of a third-order oil light is a cylinder $1\frac{3}{4}$ inches high and $1\frac{5}{8}$ inches in diameter, and the lens containing this light is constructed to give the best results from this sized flame. Now suppose two discs of carbon, each $1\frac{5}{8}$ inches in diameter, one placed $1\frac{3}{4}$ inches above the other and connected to each other by 24 carbon filaments $\frac{1}{5}$ of an inch apart attached to their peripheries, and the whole inclosed in an air-tight glass bulb, through which pass wires from each carbon disc to the source of electricity. If it be assumed that each filament can give 15 c. p., which is not an extravagant estimate, the 24 filaments should give 360 c. p., and this would raise third-order lenses to nearly an equality to the present first-order, which contain lamps of 420 c. p. Should experiment show that the above assumptions are correct, a larger incandescent lamp could be made to be used in a first order lens, which calculations show should exceed 1,000 c. p.

The incandescent lamp possesses various other advantages for lighthouse illumination which it is unnecessary to touch upon until its power can be sufficiently raised to make it an efficient light.

ESTATE OF FREDERICK A. GOWER.

Lilian Norton-Gower, known professionally as Lilian Nordica, the prima donna, has gone to Paris to claim the estate of her husband, Frederick A. Gower, who is supposed to have been lost from a balloon, as nothing has been heard of him or of the balloon since the ascension was made from Cherbourg in July. His estate is valued at $3,000,000. He made his fortune largely in the telephone, which he went to Paris some years ago to introduce into Europe soon after the successful experiments of Prof. Bell in this country. He was formerly a journalist in Providence, R. I., and as an associate of Prof. Bell lectured on the telephone before he went abroad. Mrs. Norton-Gower some time ago petitioned the court for a separate maintenance from her husband, praying that she be freed from his control on the ground of ill treatment. She said she was a native of Maine, and married Mr. Gower in Paris about 15 or 16 months ago. Mr. Gower asked for a postponement in presenting his evidence to enable him to return to Paris. He made the ascension to continue experiments to test the use of balloons for war purposes.

BEGINNING UNDERGROUND WORK IN DETROIT.

In August last the Dorsett Underground Service Company was organized in Detroit with a capital of $500.000 for the purpose of constructing a system of underground conduits like that which has been used in Chicago for a year past. Mr. Hugh McMillan is president, and the Michigan Telephone Company is represented by two out of a board of five directors.

Before granting the ordinance for a thirty-year franchise, a committee of the Detroit common council visited Chicago and subsequently rendered the following report:

To the Honorable the Board of Councilmen:

Gentlemen—Your committee on streets and ordinances, to whom was referred the ordinance for the construction and maintenance of the Dorsett conduit system, would respectfully report:

That the matter has had our careful and personal examination.

That owing to the fact that it was an important matter, your committee deemed it advisable to visit Chicago for the purpose of examining the system in practical operation, which your committee did, and are pleased to report that we found upwards of ten miles of conduit constructed by Mr. Dorsett in full operation in the city of Chicago, and that the material used in the construction of the conduit was of such a character as to render the conduit absolutely impervious to water, air or gas. From the examination made, your committee are of the opinion that it is the most perfect system now in existence, and therefore recommend its adoption by your honorable body.

Respectfully,
RALPH PHELPS, JR.,
E. P. CONAHAN,
AUGUST GOEBEL,
THOMAS M'GRATH,
THEO. RENTZ.

Accepted. The ordinance was read twice by its title, and by unanimous consent placed upon the order of third reading and unanimously adopted.

There is to be put down before December 1st six miles of

Digitized by Google

double conduit with the laterals, one tube of seven ducts for telegraph and telephone, another of the same size for electric light wires. Those of the Michigan Telephone Company will be placed in the conduit upon its completion, and applications have been made for accommodating electric light wires. The construction of the conduit has already been started.

INFRINGEMENT OF INSULATED WIRE PATENT.

A notice has been issued by the Ansonia Brass and Copper Company and Holmes, Booth and Haydens that suits will be brought against all persons using or dealing in insulated wire not made by them, or the American Electrical Works, which infringes the claims of A. A. Cowles's patent No. 272,660, as follows:

1. The method herein specified, of insulating Electric Conductors, and rendering the coating substantially non-combustible, consisting in applying a layer of fibrous material, a layer of paint, and a second layer of fibrous material upon the paint before it dries or sets, substantially as set forth.

2. An insulated and non-combustible covering for Electric Conductors, composed of two or more layers of cotton, or similar threads, with paint that intervenes between the layers and fills the interstices of the covering, substantially as set forth.

THE TELEGRAPH.

A report comes from Harrisburg to the effect that the Standard Oil Co. is about to engage in the general telegraph business.

The Baltimore police department is introducing a call-box system similar to that now used in Chicago, St. Louis and Washington. Both telegraph and telephone will be employed in connection with it.

The lodging of kite-tails on the police and fire telegraph wires in New York city, has led to the enforcement of an existing law which imposes a penalty of $5 for flying kites below 14th street

Sheriff Dewstoe, of Cleveland, O., has issued attachments on all the property of the Postal Telegraph Co. in 12 counties of the state, on a judgment against the company for $42,000 in favor of Campbell C. Brown and Thomas Fleming, holders of two promissory notes which were not paid at maturity.

ELECTRIC LIGHT AND POWER.

Domestic.

W. R. Anno, N. L. Mills, Nat. Poyntz, T. J. Shine and J. B. Paramore have organized at Orlando, Fla., the Orlando Gas and Electric Light Co., capital stock, $50,000, to establish gas and electric light works.

The Menomonie (Wis.) Illuminating Co. has filed articles of association, the object being to furnish electric light to the city of Menomonie. The capital stock is $15,000, and the incorporators are H. E. Knapp, E. Marks, S. B. French, and J. D. Hills.

The Chicago Electric Railway Co., at Chicago, has been incorporated, capital stock $10,000, for the construction of railways and tramways upon which electricity may be used as a motive power; incorporators, Wm. G. McCormick, David G. Hamilton and S. E. Stanley.

The Rockford (Ill.) Electric Light Co. has just closed a contract with the Western Edison Electric Co. of Chicago for 1,200 10 c. p. lamps. The capital stock of the company has been increased from $20,000 to $50,000. A proposition has been made to light the city which it is thought will be accepted.

The Edison company has fitted up 51 vessels with a total number of 8,092 incandescent lamps. The largest single installation is that of the steamer *Pilgrim*, numbering 920.

Foreign.

Among the awards at the Inventions Exhibition, London, were gold medals for the Edison-Swan systems of electric lighting and the Thomson-Houston; silver medal, the Bernstein incandescent lamp.

Machinery is now in readiness to illuminate Dufferin terrace in Quebec, by electricity generated by water power at Montmorency Falls, over a circuit 34 miles in length.

PERSONAL MENTION.

Thomas D. Lockwood, of the American Bell Telephone Co., will lecture on the telegraph and telephone, next winter, before the Lowell Institute, of Boston.

THE TELEPHONE.

The Charleston (S. C.) telephone exchange property was damaged to the amount of about $4,000 by a recent tornado.

A large proportion of rural exchange subscribers in New England are discontinuing the service in consequence of the recent increase in rates.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER *by* Pope & Edgecomb, *Solicitors of Patents for Electrical Inventions,* 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From August 18th to September 15th, 1885 (inclusive).

Alarms and Signals:—*Annunciator*, R. Edwards, 324,869, Aug. 18; H. E. Waite, 325,463, Sept. 1. *Indicator*, M. Bacon, 324,635, Aug. 18. *Alarm* J. J. Wood, 325,639, Sept. 1. *Sewer*, J. H. Clark, 325,820, Sept. 8. *Shallow Water Indicator*, F. E. Forster, 326,028, Sept. 8. *Signaling Apparatus*, F. G. Sargent, 326,158, Sept. 15.

Clocks:—*Impulsion Device for Torsion Pendulum*, H. Rabe, 325,118, Aug. 25. *Clock*, F. R. Field, 324,824.

Commutators:—*Circuit Closer*, A. T. Smith, 325,124, Aug. 25.

Conductors, Insulators, Supports and Systems:—*Terminal for Electric Light Cables*, W. R. Patterson, 324,413, Aug. 18. *Method of Temporary Electric Lighting*, L. Goldenberg, 324,551, Aug. 18. *Insulator*, G. W. Hill, 324,692; J. D. Putnam, 324,957, Aug. 25. *Conduit for Cable and Electric Railways*, I. W. Heysinger, 325,173, Aug. 25. *Circuit for Electric Lighting*, H. P. Brown, 325,389, Sept. 1. *Arc and Incandescent System*, 325,390. *Incandescent System*, same, 325,391. *Underground Conductor*, D. Brooks, 325,495 *Socket and Connection for Lighting Circuits*, G. Hess, 325,540. *Insulating and Anti-Induction Tube for Conductors*, F. B. Rae, 325,630. *Machine for Covering Wire*, V. & J. Royle, 325,363. *Combined Track Support and Conduit*, J. H. Gould, 325,531. *Method of Laying Wires*, W. D. Smith, 325,984, Sept. 8. *Supporting Wires*, M. Heltinger, 325,743. *Die for Covering Wire*, G. M. Cruickshank, 326,021. *Method of Applying Balata Insulation*, P. C. Matherson, 326,132, Sept. 15.

Dynamo Machines and Motors:—*Regulator for Dynamos*, E. Thomson, 324,501, Aug. 18; P. Diehl, 324,666; R. H. Mather, 324,862, Aug. 25. C. J. Van De Poele, 325,133. *Current Regulator for*, J. A. Lannert, 324,566, Aug. 18. *Commutator Brush for*, J. A. Powers, 324,590. *Dynamo Machine*, H. Cushman and J. P. Hall, 324,752; C. L. F. Mueller, 325,619, Sept. 1. *Motors*, P. Diehl, 324,667, Aug. 18; L. G. Woolley, 325,641, Sept. 1. F. J. Sprague, 324,891, Aug. 25. *Armature for Dynamos, and Motors*, S. F. Van Choate, 325,714, Sept. 8. *Automatic Stop Apparatus for Motors Driving Dynamos*, O. F. Jönsson, 326,223, Sept. 15.

Galvanic Batteries:—*Connector for Batteries*, G. Otto, 324,410, Aug. 18. *Galvanic Battery*, W. T. Lyman, 324,475; E. F. Leighton, 324,708; J. B. Low 324,858, Aug. 25; E. G. Hammer, 326,033, Sept. 8.

Ignition:—*Gas Engine*, C. W. Baldwin, 325,378, Sept. 1. *Gas Lighter*, F. H. Root, 325,569.

Lamps and Appurtenances:—*Holder for Incandescent Lamps*, F. M. Brown, 324,580, Aug. 18. *Arc Lamp*, O. P. Loomis, 324,778; A. B. Worth, 324,793; E. Thomson, 324,502, A. H. Bowman, 324,798, N. McCarty, 325,423, 325,424, Sept. 1. Geo. M. Hopkins, 325,802, Sept. 8; R. F. Jones, 326,123, Sept. 15; J. Du Shane, 326,487. *Socket for Incandescent Lamps*, W. Stanley, Jr., 324,894, Aug. 25. *Alternating Switch for Incandescent Lamps*, J. A. Cabot, 324,979. *Safety Device for*, same, 324,980. *Process of Making Incandescents*, same, 324,981. *Manufacture of Incandescents*, P. N. Mackay, 325,257, Sept. 1. *Incandescent Lamp*, O. A. Moses, 325,958, Sept. 8, *Lamp Hanger*, W. S. Weston, 326,363, 326,364, Sept. 15. *Bulb Case for Incandescent Lamps*, S. H. Sprague, 326,459. *Arch for Supporting Lamps*, P. H. Griffin, 326,498.

Measurement:—*Meters*, W. G. Price, 325,011, Aug. 25; C. J. Van De Poele, 325,225. *Apparatus for Testing Circuits*, I. H. Farnham, 325,520, Sept. 1.

Metallurgy:—*Process of Smelting Ores*, E. H. and A. H. Cowles, 324,658, Aug. 18. *Process of Smelting for Obtaining Aluminum*, same, 324,659.

Miscellaneous:—*Type Writer*, J. R. Murphy, 324,407, Aug. 18. *Hydrostatic Testing Machine*, W. R. Patterson, 324,412 .*Elevator*, S. S. Wheeler, 324,621, Aug. 18. *Contact Point*, E. T. Gilliland, 324,678. *Electric Belt*, O. F. Main, 324,713, L. Hughes, 325,086, Aug. 25. *Safety Device for Elevators*, R. M. Curtiss, 324,751, Aug. 18. *Automatic Specific Gravity Apparatus*, G. A. Bobrick, 324,808, Aug. 25. *Regulator*, W. Stanley Jr., 325,576, Sept. 1. *Switch Plug*, J. H. Bunnell, 325,653, Sept. 8. *Process of Making Plates of Carbon*, S. J. Coxeter and H. Nehmer, 325,822. *Electro-Magnetic Log*, L. B. Favor and C. A. Jacobs, 326,207, Sept. 15. *Induction Coil*, W. Burnley, 326,270. *Electrical Apparatus for Controlling Marine Engines*. L. M. Sanders, 326,337. *Organ Action*, G. G. Wacker, 326,359. *Safe*, O. Gassett, 326,424.

Railways and Appliances:—*Telegraph*, E. B. Ives and C. W. Williams, 324,381, Aug. 18. *Apparatus for Propelling Vehicles*, F. Wynne, 324,447, Aug. 18. *Car Brake*, E. B. Hess, 324,470, C. E. Jones, 324,774. *Railway Controlling System*, C. A. Mayrhofer, 324,476. *Motor*, F. J. Sprague, 324,892, Aug. 25. *Railway*, C. J. Van De Poele, 324,899, Aug. 25. *Conductor for*, John Hopkinson, 325,063, J. Perry and W. E. Ayrton, 326,237, Sept. 15. *Lighting Railway Cars*, H. E. Freese, 325,795, Sept. 8. *Locomotive*, L. Daft, 325,915. *Signal*, I. A. Tivamis and C. C. S. Currie, 326,068.

Storage Batteries:—J. S. Sellon, 324,597, Aug. 18; 325,120, Aug. 25.

Telegraphs:—*Cut-out*, C. H. Lothrop, 324,711, Aug. 18. *Magneto-Electric Telegraphy*, F. H. Brown, 324,746. *Telegraphy*, W. E. Athearn, 324,799, Aug. 25. *Printing Telegraph*, R. J. Sheehy, 325,702, Sept. 8. *Controlling Press Circuits of Printing Telegraphs*, C. L. Healy, 326,084.

Telephone Systems and Apparatus:—*Acoustic Telephone*, W. T. Black, 324,356, Aug. 18; J. B. Cleaver, 325,500, Sept. 1; H. Seligman, 326,458, Sept. 15. *Telephone Switch*, J. A. Cabot, 324,358, Aug. 18. *Telephone System*, C. W. Price and A. Barrett, 324,591, A. E. Dolbear, 325,659, Sept. 8. *Transmitter and Relay*, T. J. Perrin, 324,726, 324,727, Aug. 18. *Transmitting Apparatus*, 324,728. *Transmitter*, T. J. Perrin, 324,729, W. Burnley, 326,269, Sept. 15. *Means for Increasing the Efficiency of Telephones*, A. E. Dolbear, 325,660, Sept. 8. *Telephone Repeater*, M. G. Farmer, 325,920. *Switch-Board Plug*, C. K. Mead, 325,952. *Receiver*, W. Burnley, 326,268, Sept. 15.

Expired Patents.—A list of the more important electrical patents which expired during the month of September, 1885, together with those which will expire during the present month is subjoined:—P. A. J. Dujardin, *Printing Telegraph*, 82,502; reissue 7,627, Sept. 29.—A. Barbarin, *Gas-lighting Apparatus*, 81,785, Sept. 1.—R. B. Boyle, *Printing Telegraph*, 81,871, Sept. 8.—E. Beach, *Torpedo for Oil-Wells*, 82,586, Sept. 29.—L. H. Reynolds. *Self-Adjusting Relay*, 82,629, Sept. 29.—S. F. Day, *Telegraph Instrument*, 82,695, Oct. 6.—S. C. Bishop, *Insulating Compound*, 83,031, Oct. 13.—G. M. Thompson, *Wire-Stretcher*, 83,109, Oct. 13.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

NEW YORK, NOVEMBER, 1885.

WAITING FOR THE VERDICT.

THE ultimate day has arrived, when, according to the original Daly bill, all wires, wherever found overhead in cities of 500,000 inhabitants or upwards in the state of New York, were to be removed and placed underground by the authority of the state. At the time the interest awakened in this discussion was greatest, we ventured the prediction that on the first day of November, 1885, there would be more wires overhead than existed at the time of writing. Such is notoriously the case, yet the date mentioned marks a certain amount of progress. Official investigation on the part of the commissioners appointed to enforce the law, has in every particular confirmed the assertions previously made by electrical experts, that there were serious difficulties to be encountered, and that strict compliance with the original act would at a blow deprive the business and resident public of the facilities for electrical communication which they have long enjoyed.

The arbitrary provisions of the bill which aroused so great an opposition from the various companies interested, as well as from the electrical press, was materially modified by the subsequent act of June 15th, 1885, by which the commissioners are allowed to exercise their discretion in compelling the adoption of subterranean routes, and the solitary subscriber, who has no telephonic neighbor within 18 blocks, may not be called upon to bear the expense of either constructing or paying rental for a mile or more of conduit constructed for his special benefit.

The popular idea of placing wires underground according to the teachings of the daily press, is simply to take them off the poles, tie them in convenient bundles and bury them at the bottom of a ditch. A similar view of the problem was taken by at least two of the inventors who submitted underground plans to the commission. This is by no means an enlightened view of the situation, as progress is desired above all things, and the electrical condition of aerial wires in New York city to-day is by no means as satisfactory as might be inferred from the opposition of the various companies toward the enforcement of the underground law. They act simply upon the familiar maxim that it is "better to bear the ills we have, than fly to others we know not of." The first subterranean work undertaken some ten years ago by the Western Union company was done voluntarily, in the confident belief that a system of that character would be exempt from the well-known evils which attend aerial electrical communication in densely populated districts. Advantage was taken of European experience in the same line, and while the results have by no means been entirely satisfactory, it is far from the truth to assert, as has been more than once done, that these experiments were made merely to prove that wires could not be successfully operated underground. It will no doubt be admitted that the recent sessions of the New York commission on electrical subways afforded an opportunity for every plan to be presented, and the substantial reward awaiting the successful competitor is no doubt sufficient to bring out the best existing ideas on the subject, yet not a single system was presented which did not have its defects. Of course very many of them were wholly impracticable, either from a mechanical, electrical or financial standpoint, while others might perhaps serve the purpose more or less well but had not received practical endorsement. A large proportion of the plans proposed did not in fact come under the provisions of the law, and might without impropriety have been ruled out altogether.

A gentleman who has given this subject very thorough study for several years, informed the commission that a conduit was merely a hole through the ground, while the *New York Times*, which has perhaps been the foremost advocate of underground schemes, declared editorially a few days since that "nothing is more unreliable than a hole in the ground."

None can be more thoroughly aware of the defects and weaknesses of existing electrical systems than those who have had the greatest experience with them. Knowing the difficulties of maintaining the electric service at a high point of efficiency under its present conditions, they do not feel disposed to admit that any plan is perfect which they have not personally tested, although it may prove better adapted to their purpose than they suppose. An experienced spiritual expert once ventured the opinion that no whiskey was absolutely bad, although undoubtedly some brands of whiskey were not so good as others. By the same line of reasoning it may well be argued that no subterranean system is good, although some plans are worse than others.

October 15th, 1885 was the last day for the filing of plans with the Board, and those which were received before the adjournment are to be examined in executive session and finally passed upon.

Such being the condition of affairs; the evidence all in, and under consideration, advice and criticism may properly be reserved until a verdict has been given. From the very nature of the case there will be disappointment and unjust accusations, but if the commissioners give their decis-

ion in accordance with what has practically proved the best, so far as they can ascertain, they will have at least performed their duty, and may well content themselves by the reflection, that despairing of any light from the conflicting theories of the various inventors and promoters, they fell back upon their own judgment, and in accordance with the law and the evidence, decided how in their opinion, a hole in the ground could be most economically made and effectually maintained, without detriment to the existing electrical service, while at the same time giving due consideration to future growth.

THE GOVERNMENT AND THE TELEPHONE PATENTS.

Referring to the proceedings instituted by certain law officers of the government for annulling the Bell patent, we said last month that the personal interests of attorney-general Garland were so clearly of a character to profit by the successful issue of such an action that an immediate and complete explanation on the part of that official appeared to be necessary. A few days afterwards the explanation appeared in the form of a letter, addressed by the attorney-general to the president, and given to the press, the substance of his statement being that he had no personal knowledge of the action which had been taken; it appearing that the application was in fact made to solicitor-general Goode, and the request was granted by him in the absence of the attorney-general. The attorney-general further explains that the solicitor-general is not a deputy or agent, but acts by the authority of a commission directly from the people through the president; that he is not therefore responsible to the attorney-general, nor can the latter exercise any control over his discretion. In reference to an inquiry by the president as to the ordinary course of procedure in such cases, the attorney-general admits that it has been the practice to first refer all such questions to the department from which the original transaction emanated. Accompanying this document was a letter from president Cleveland to solicitor-general Goode, accompanying the statement of attorney-general Garland, and somewhat pointedly calling his attention to the fact that the reference to the Interior department as an ordinary feature of the procedure, seemed to have been dispensed with in the treatment of this application, and suggesting whether such action as will preserve such precedent and custom might not well be taken. In reply to this communication the solicitor-general explains that his reason for granting the application without the usual reference to the Interior department was the result of "a satisfactory persuasion derived entirely from the papers" presented to him "as to what was right and proper to be done in the premises." The papers appear to have consisted of affidavits furnished by district attorney McCorry, and a certified copy of the proceedings in the patent office in relation to the issue of the Bell patent, which papers, he says, seemed to contain all the necessary information. Nevertheless, the solicitor-general states in conclusion, that he has directed district attorney McCorry to discontinue the suit. Thus ended the first chapter of the history of this peculiar case. The explanation of the attorney-general, while perhaps technically sufficient, is not altogether satisfactory, but it is far more so than the explanation of solicitor-general Goode. If, as his letter states, he had given the papers a careful examination, it surely ought not to have escaped his notice that the most important allegation of the bill, viz.: that Bell had altered his pending application in consequence of having fraudulently obtained a knowledge of the contents of papers filed by a rival inventor, was absolutely false. The remarkable haste which was exhibited in granting leave to district attorney McCorry to institute the suit, which, if we are rightly informed, was the very next day after the application was made, seems to indicate that there may have been some peculiar reason for the unusual zeal of the solicitor-general.

No sooner, however, had the original suit been discontinued as above noted, when district attorney McCorry again applied to the department of justice for permission to bring a new suit in the name of the government to test the validity of the Bell patent, which application has, it appears, been referred to the commissioner of patents for the purpose of obtaining his opinion as to whether the proposed proceedings were justifiable. As the attorney of the Pan-Electric Telephone Company is said to be in attendance at Washington, it is probable that the commissioner will not be deprived of any assistance he may need in making the examination. It appears, furthermore, that the Globe Telephone Company of New York has filed a petition for the commencement of another similar suit by the government against the Bell patents, which has also been referred to the commissioner of patents.

The present indications are that the whole matter will ultimately become a partisan political issue. It is rumored that the political opponents of the attorney-general propose to examine the transaction whereby he received a million and a half of telephone stock while acting as a United States senator, and at the time of writing it seems not unlikely that an attempt will be made to investigate the whole business by means of a congressional committee.

It is believed by many that the original suit had no other object than to afford a plausible pretext for the refusal or postponement of injunctions which might be applied for by the American Bell Telephone company in the United States district courts against alleged infringers, claiming to act under the authority of the Pan-Electric Telephone Company. In the Baltimore case to which we alluded last month, this course of procedure seems nevertheless to have proved ineffective, and in fact we do not see how the decision of the court could well have been otherwise, for if such a precedent were once admitted, we should soon have the federal courts overrun by suits in which the United States would practically be both plaintiff and defendant, and it would be in effect impossible for patentees to secure any adequate protection against even the grossest infringements.

LOCAL TELEGRAPHY IN NEW YORK CITY.

The president of the Western Union Telegraph Company in a recent statement, frankly admitted that the local telegraph service in London was superior to that of New York, and furthermore announced that in his opinion the latter might be improved. Although no reason was given why this most desirable consummation cannot be reached, it may

Digitized by Google

fairly be presumed that it is because it does not pay. Branch offices are established for the purpose of securing out-of-town rather than strictly local business, and as no additional rate is charged from these offices the expense of performing the service is increased by the necessary re-transmission of the telegram.

It is well understood by those who are familiar with telegraph business either professionally or as patrons, that communication with distant commercial centres is much more prompt than between points within the city limits. There are a number of reasons for this apparently anomalous condition of affairs. President Green gave but one, which was that there were in some cases eight or ten offices on one wire, and a message might be delayed by the operator waiting for his turn. He might have truthfully added that with a better class of operators, the time of waiting might be materially reduced. This however is a characteristic feature of the modern telegraphic system, which according to other eminent authorities is a vast training school, from which the graduated experts are continually being drafted into other fields which are believed to offer greater inducements by reason of their placing a higher value on experience.

No city in America offers such inducements for intercommunication as New York. The local postal service with an army of carriers, each of whom receives a salary equivalent to that of a good Morse operator, pays a handsome revenue, although it was not established "for revenue only," but as a desirable adjunct to the general postal service. Private letter-carrying establishments also carried on a prosperous business in competition with the government until suppressed by law. At least four district telegraph companies are engaged in a similar line of business. As to their profits we confess our ignorance, but in this particular branch it is patent to everybody, competition has not by any means developed an improved service. The telephone has also found ample room to build up an immense business in the local field, and while this agency is criticised because of the high prices charged for its use, we have no doubt that most of its subscribers save in car-fare, messenger hire and postage, a considerably greater amount of cash than they pay for its use. The elevated railways, and their new rival the Broadway line of horse-cars, are also no small factors of progress in local intercommunication. Amidst all these changes local telegraphy, even if it has been improved, which we are not prepared to admit, has by no means reached that state of perfection which can at least be imagined. This is a field which might not only be developed in itself, but would gradually familiarize the people with the use of the wires, and thus popularize the whole service. If this branch of the business was put in the hands of a wide-awake, intelligent, progressive telegrapher, familiar with the public requirements, and with authority to locate offices, engage competent operators, and advertise thoroughly, it appears to us that it would prove directly and indirectly a profitable department of this business. As it exists to-day it is practically a delusion and a snare. A fee of ten or fifteen cents is accepted for a service that in speed is inferior to that of the slowest messenger on foot, while the amount charged is so insignificant that a customer prefers to lose it rather than undertake to have it refunded in case of unreasonable delay. The local service necessarily costs as much, if not more than the long line service, and it is probably useless to try to perform it at a cheaper rate. Any reasonable rate would be cheerfully paid if the service were what it should and might be made.

This is a field however, to which the pneumatic tube system is more properly adapted, but to make it sufficiently comprehensive to meet the demands of the public in every part of the city, would incur an outlay for plant which no capitalist would care to risk. The tubes now used are merely auxiliary to the telegraph service, and are intended rather as feeders for the main office than for local intercommunication.

THE FINANCIAL RESULTS OF TELEGRAPHIC COMPETITION.

The annual report of the Western Union Telegraph Company, which we publish in another column, shows that its competitors are making formidable inroads upon its revenues. The report states that the profits for the fiscal year just closed, from which a dividend on $80,000,000 is to be paid, were actually less than in 1880, when the capital stock was only $41,000,000 ; the precise figures being $5,700,924.13 as against $5,833,937.79, although the actual number of messages transmitted had increased 44.3 per cent. and the mileage of wire no less than 98.2 per cent. The natural growth of the business transacted by the company has been very seriously interfered with by the competition of the past three years. For instance, the increase in the number of messages handled over the previous year, was in 1882, 6,342,000; and in 1883, 2,340,000; in 1884, 895,000, and in 1885, only 20,357. From these figures it seems certain that at the present rate of decline in its revenues, the Western Union must within a short time materially lower its rate of dividends, especially as the report indicates that the amount of money ordinarily spent for reconstruction, repairs and maintenance, has been largely curtailed, although the amount thus saved must necessarily be expended within a few years. As matters are going on at present, there is very little profit for anybody in the telegraphic business, but a change of some kind must inevitably be brought about at no distant day. We venture to express the prediction that the ultimate outcome of the present unsatisfactory situation, will be some sort of a pooling agreement based either upon the gross receipts, or the number of telegrams transmitted by the respective companies. Such a programme would obviously be to the advantage of the Baltimore and Ohio, but it is not altogether clear how the old company, under existing conditions, can manage to bring about any other arrangement which would be more favorable to its own interests.

The loss of revenue occasioned by the leasing of wires to parties who had previously been large patrons in the ordinary manner, is a significant feature in the report. It appears strange that little profit is derived from this source, as the cost of construction and maintenance of such wires is so well known, and was doubtless fully considered when the rental prices were fixed. Having in mind the many economies which have been practiced in order to maintain the financial standing of the company, and also that the increase of business from lower rates is not sufficient to encourage their further reduction, it certainly appears that the limit of healthy competition has actually been passed.

ELECTRIC TRAMCARS.[1]

BY A. RECKENZAUN.

It may be premature to read a paper on the subject of electric tramcars, considering that at this moment there is only one such car in existence in this country, so far as the author is aware. This solitary example has, moreover, only been in operation experimentally since October last. It was with considerable hesitation, therefore, that this paper was prepared at the invitation of the council of this institute. The Inventors' Institute has, nevertheless, the privilege before other societies in this respect, that it will judge of the merits of an invention as an invention, apart from the commercial aspect of the problem. Utility, however, is the first desideratum in an invention, and the author now merely submits to this institute the bare question of utility. Before going into the details of our subject, it may be interesting to dwell for a moment upon the figures in the table below, which was prepared in order to show what power a pair of horses are capable of exerting. The power exerted in propelling a 46-passenger car, tractive force 30 lbs. per ton, two horses pulling 4.5 tons, is at—

		Horse-power.
7 miles per hour on level road		2.52
6 " " " "		2.16
6 " " on a gradient of	1 in 75	4.32
5 " " " " "	1 " 37	5.4
4 " " " " "	1 " 37	4.32
3 " " " " "	1 " 25	4.32
4 " " " " "	1 " 25	5.76
5 " " " " "	1 " 25	7.2
3 " " " " "	1 " 18	5.4

The additional power necessary to pull a car round curves cannot be ascertained with equal accuracy; it depends upon the radius of the curve, the amount of play in the axle boxes, and the size of the wheel flanges; a flexible wheel base will considerably facilitate the movement on curved roads.

STARTING FORCE.

The force required to start a car and to get up speed is necessarily greater than that required to maintain the speed uniformly. "It is a variable quantity," says Mr. D. K. Clark, in his admirable book on tramways, "for it may be anything that horses choose to exert." But it has been found by experiment that the momentary starting force is about four times the tractive force when once in motion; thus we may form a rough idea as to the exertion of a horse in starting a car on the level or on an incline. Horses cannot tell us of their sufferings; we know, nevertheless, that their life in the tramway service is but short, although they work no longer than three to four hours a day. It is barbarous to use horses, as these figures show, yet there has been until recently no economical substitute, and it is only within the last few years that mechanical traction has made any headway. That mechanical power will supersede animal power, and that at no distant date, is admitted on all hands, but the question of the kind of mechanical power to be employed is still an open one. It is often asked why so much mechanical power is required for the propulsion of tramcars, and why it is that a tram locomotive should be made to give as much as 40 indicated horse-power and more, whilst two horses seem to do the same amount of work.

The above table shows what mechanical work is actually being done. James Watt ascertained experimentally that a strong dray horse is capable of producing a continuous effect of 33,000 foot-pounds per minute; but we see that one tram-horse does the work of three or four dray horses very frequently. When we consider that a tramway steam-locomotive often weighs from 8 to 10 tons without the car and passengers, it becomes evident that the indicated horse-power above given is no extravagant measure. Take a locomotive, car, and passengers as weighing together 13 or 14 tons, then, in order to move that load on a level road at a speed of 7 miles per hour, with a tractive force of 30 lbs. per ton, we require from 7 to 8 actual horse-power, which is equivalent, after allowing for engine friction, to about 11 indicated horse-power; and, when traveling up an incline of 1 in 37, something like 34 indicated horse-power. Reducing our figures to a co-efficient, and maintaining that the tractive force is 30 lbs. per ton on a level but dirty road, we come to the conclusion that, when moving at a rate of 7 miles per hour in a straight line, we shall consume 8 foot-pounds of work for every pound of weight on the rails; on an incline of 1.75 we consume 16 foot-pounds, and on an incline of 1.37, 24 foot-pounds for every pound weight carried at the same speed. Therefore it is of the utmost importance to reduce the dead weight to be propelled to a minimum. Where the locomotive engine has to drag the car behind it, it becomes necessary to provide weight in order to obtain good adhesion on the rails, and the best plan, no doubt, would be to utilize the weight of the car and passengers for this purpose.

The number of steam locomotives employed on tramways is daily increasing, and steam traction is gaining in public favor. It is not, however, within the range of this paper to examine into the advantages or disadvantages of steam traction; but merely to show whether electric tramcars have any chance of success from a utilitarian point of view. We distinguish between the terms electric cars and electric tramway or railway; the electric car carries its energy within itself, and is quite independent of external influences; whereas, in electric tramways, the energy, electricity, is conveyed from the generating station to the rails or other conductor communicating with the motor which turns the car wheels. Separate conductors are used by Messrs. Siemens, at Portrush or elsewhere; Mr. Magnus Volk, at Brighton, conveys the current through the rails—the nature of the ground (shingle) on Brighton beach does not allow of any accumulation of rain or dirt, the rails are above ground, and there is no traffic across the line; an electric tramway is being constructed at Blackpool, where current is conveyed through conductors in a pipe laid underground between the rails; this pipe has a slot throughout the whole length to permit of the connection between the car motor and the conductor beneath the surface of the road. Our electric car, as the model shows, requires no conducting medium; it does not interfere with the rails or roadway nor with other traffic, and it can be shifted from one line to another of the same gauge, it can be run in conjunction with the ordinary horse-cars.

THE BATTERY.

In order to make an electric car, we require a battery which can be stowed away within the car. Such battery has to be of small weight, must be reliable, supply any quantity of current according to the exigencies of the road, must be cheaper than horse flesh, and emit no smell. Primary batteries are out of the question; the cost of zinc consumed in them would be much greater than that of animal power, independent of the difficulties attending the process of refilling such batteries when exhausted. The invention of the secondary (storage) battery put the question entirely in a new light; certain successful laboratory experiments at once suggested the adaptability of this invention to the propulsion of vehicles. Four years have elapsed since the introduction of the Faure accumulator into this country. It caused quite a sensation at that time, and money could be found in abundance for the exploitation of anything that bore an electrical name. Things have changed entirely since then. The original Faure battery has never been of any practical use, and very substantial improvements had to be made, at enormous expense, to bring the secondary battery to a commercial value. The Electrical Power Storage Company have acquired the patent rights of M. Faure; in addition to those of Messrs. Sellon, Swan and

[1] Paper read before the Inventors' Institute [England]. From *Iron*.

Digitized by Google

Volckmar, and they have, step by step, improved the mechanical details of these storage batteries, until they arrived, after immense labor, at what may be termed a thoroughly practical article. But the prejudices created in the public mind by early failures have not quite worn off yet, and it will require something wonderful and startling to convince the public that the work of the last four years has produced remarkable and practical improvements.

None but those who have been intimately connected with the manufacture of storage batteries can form an adequate idea as to the numerous difficulties which had to be surmounted before a permanent success was attained. The battery was long perfect from a theoretical point of view, but it could not stand the test of time—time was an essential factor; it took many months to test the durability of a set of cells, and it was only by close observation and careful remedying of defects, one by one as they appeared, that the storage battery assumed its present form—simple as they may appear to the uninitiated. The cell before you is one of a set of the type specially designed for tramcar work. In a lead-lined strong teak box are placed twenty-one lead plates, weighing together 26 lbs. inclusive of connecting strips and terminals. Ten of these are called positive, and eleven negative. Each plate is formed of a leaden grid, the perforations of which are filled with a paste of lead oxide; the positive plates contain red lead, which, in charging, is converted into peroxide; the negative grids are filled with a paste of litharge, which, in charging, is reduced to spongy lead capable of absorbing hydrogen. We store, therefore, not electricity, but oxygen and hydrogen, which gases, when the battery is discharging, manifest themselves externally in the form of electrical energy. The box is filled with sulphuric acid and water of a specific gravity of about 1150°; then a lid is put on, sealed all round the edges to prevent any spilling of the acid. This acid is never removed so long as the battery lasts. There is no reduction of lead or any material going on within the cell, and the battery would last forever, but for the fact that the lead grid of the positive plates becomes so brittle through oxidations that it crumbles to pieces in course of time; then, these positive plates have to be replaced periodically by new ones; but the old lead is valuable. The life of a positive plate depends entirely upon the amount of work it has done. The plates in the box before you have been at work since September last, and are still in excellent condition—we should say they are still as good as new. They have frequently been discharged at the rate of 100 ampères, whilst the average working current is 46 ampères, they are always charged at the rate of 32 ampères, and their storage capacity is 150 ampère-hours. Sixty such cells will weigh 1¼ ton, and propel a car with forty-six passengers for about two hours over a road with ordinary gradients, curves, and sixty stoppages per hour.

The diagram (which was exhibited by the lecturer) represents such a car, which has been running at Millwall and at Battersea. The accumulators are placed on trays under the seats out of sight. These trays can be drawn out through doors at one end of the car, and replaced in a few minutes. A trolly containing a fresh set of trays and rollers is drawn up to the end of the car. The discharged cells are pulled out all together by means of a small winch, and the newly-charged cells pushed in, when the car is at once ready to proceed on its journey. There are three sets of accumulators to each cars, two sets being charged, while one set is propelling the vehicle, thereby saving time and preventing delay.

THE ELECTRO-MOTOR.

This machine has to convert the electric current into mechanical power. For tramcar propulsion it is absolutely necessary that the motor should have a high efficiency, and, at the same time, be of small dimensions and of light weight. To combine these requirements has been the aim of the author, and he has, at length, produced a machine which has had some rough tests in actual service under the most trying circumstances and conditions. There are two motors driving the car, each capable of working up to nearly 9 h. p. and weighing 420 lbs. Each motor is supported independently upon a small bogie; the whole mechanism is self-contained; and each separate bogie forms a small locomotive engine, upon which the car rests. One axle of each bogie is a driving-axle. Thus we obtain four small driving-wheels, which give the requisite grip upon the rails. Either bogie can be detached from the car in less than one hour, so that in case of repair and inspection the motor can be taken out and replaced without letting the car stand idle for any length of time. The speed of the motors is high, about 1,000 revolutions, when the car is running at 7 miles an hour; thus it is necessary to introduce some mechanical reducing gear between the motor-shaft and the driving-axle.

THE GEARING.

The gearing so employed consists of a worm on each motor-shaft and worm-wheels on the driving-axle giving a ratio of about 1.12. This worm-gearing is boxed in, as likewise is the motor, and the wheels run in oil, dirt is thereby excluded, and the lubrication kept perfect. Easy access is obtained to motors and lubricators through doors in the floor of the car.

VARIATION OF SPEED AND POWER.

This is obtained by means of a compound switch, which arranges the motor-circuits so that the machines shall work in series, in parallel or singly; thus the resistance of the circuit being varied, the power and the speed vary accordingly. When a greater range of speed is desirable, the motor-circuits are still further divided by arranging the field magnet wires apart from the armatures. This obviates cumbersome gearing, which would add to the weight and the expense also—increase first cost and maintenance as well. The driver has full command over the motive power; one handle sufficing for all the operations of starting, stopping, and varying the speed or power. There is no useless electrical resistance, and, therefore, no waste of energy, whatever speed the car may be traveling at. The car is provided with these details at both ends, so that the driver has only to remove the handles and two connections when arriving at the journey's end, and then proceeds. It would be an easy matter to vary the speed by decreasing or increasing the number of cells, thereby varying the electromotive force; this method, however, is injurious to the accumulators, because some of the cells would be discharged sooner than the others, and when they are all recharged in series, some would have to be very much overcharged before the rest could receive their proper share. There would be not only a waste of power occasionally by the evolution of gases for no purpose, but the life of the cells and their efficiency is reduced by this irregular treatment.

THE BRAKE POWER.

At each platform there is the usual vertical shaft and brake-handle. A chain is wound upon this shaft when the handle is turned, and eight brake blocks are simultaneously pressed against the corresponding number of wheels. The car can be stopped almost instantaneouely; but beside this there is an electrical brake, so that the motors act as dynamos driven by the momentum of the car or by the car running down an incline; the whole power stored up in the momentum of the car is converted into electricity and the current generated is utilized in magnetizing the brake-blocks, thereby increasing their grip upon the wheel tires. Arrangements are being made to render this electric brake automatic, so that the main circuit will be broken and the brake-circuit with the motors closed automatically when the speed of the car attains a certain maximum.

COST OF MOTIVE POWER.

It has been mentioned that the capacity of the tramcar cells is 150 ampère-hours. We do not exhaust them en-

Digitized by Google

tirely, but leave a margin of at least 20 per cent. in the cells. A charge of 120 ampère-hours is sufficient to propel the car full of passengers for two hours, or about 12 miles over an average road with frequent stoppages. When charging 60 cells at the rate of 32 ampères for four hours, and replacing the accumulators in the car every two hours, we require steam power to the amount of about 1 indicated h. p. per car. Assuming that the car has to run 72 miles a day, and that we are supplying several cars at the same time from one engine, the fuel consumed need not exceed 4 lbs. per indicated h. p. per hour. The charging takes place during 12 hours of the day only. Thus 7 cwt. of coal per car per day will give a consumption of about 10 lbs. of coal per mile. Reckoning the price of coal at 18s. per ton, the fuel per car-mile would cost less than one penny ! By working longer hours, we could do with smaller engines, but, of course, with the same consumption of coal per car-mile. The most economical steam tramway locomotives burn from 9 to 11 lbs. of coal per mile, or about the same as quoted for the electric car. There are two reasons for this consumption. Firstly, the steam locomotive weighs four times as much as the accumulators and electric motor and driving gear—therefore, it requires greater power for its own propulsion ; secondly, a tramway locomotive boiler and engine cannot be expected to compete with a large stationary engine as regards economy. The loss thus arising from the conversion of steam power into electricity, and the reconversion of electricity into mechanical power is more than compensated by corresponding advantages. There are instances where water power is available within a reasonable distance from the tramway depot, in which cases the additional economy will be manifested.

PRIME COST, MAINTENANCE AND DEPRECIATION.

The steam engines, boilers, dynamos, and shafting, and all needful apparatus for a charging station to supply a dozen electric cars, including spare power, will cost £4,000, and the complete equipment of 12 two-horse cars, inclusive of ample spare gearing, may be estimated at £6,000. The superintendence of machinery at the charging station will cost £1,100 per annum ; fuel at 18s, per ton, water, oil, and waste, £1,400 ; depreciation, at 10 per cent., on engines, boilers, and dynamos, £400 ; and an estimated depreciation of 35 per cent. on the whole propelling apparatus. This gives a total expenditure of £5,000 per annum, which is equivalent to 3.5d. per car per mile run. You will observe that these figures are thoroughly reasonable and allow of a good margin. We should have almost to annihilate the whole concern at the end of a year in order to bring the working costs to such an amount as is now allowed by some tramway companies for horsing !

SUMMARY.

I have pointed out the chief but yet only a few of the advantages of this system over horse traction, and I will in a few words enumerate them :

1. Economy in cost of running, which is estimated at about 3½d. per mile, including depreciation.
2. The appearance is that of the cars now in general use, and these latter can be readily converted.
3. The wearing parts of the mechanism which drives the wheels are few in number.
4. The total weight of the motive power mechanism is less than two tons distributed over two small bogies, whereby the load per unit of rail section is rendered even less than in the case of horse cars.
5. The propelling apparatus is invisible to the passengers, noiseless, clean, and perfectly safe.
6. One man (not necessarily skilled) is sufficient to drive an electric car.
7. The car may be illuminated at night by the electric current sufficiently to enable the passengers to read with comfort, while effecting a saving over oil lamps in cost and avoiding their dirtiness. The power required is so small that the cost may be neglected; the 20-c. p. lamps used consuming only three ampère-hours out of the total of about 150 ampère-hours given by the cells.
8. The maintenance of the permanent way (including paving) is less than with horse cars, where the hoofs are continuously striking in the same tracks. Existing rails will serve for the electric car of this system, and no additional rail or tube or breaking up of the road is necessary, preliminary to its adoption.
9. The space required for a charging station is much less than that necessary for stables for a corresponding number of horses.
10. The same plant which charges the storage batteries may be utilized for lighting the depot and other neighboring buildings by running extra hours at trifling further cost, thus yielding additional revenue.

DISCUSSION.

Professor George Forbes, F. R. S. E., gave a short and concise account of the electric railways laid down in various parts of the world within the last few years, and he considered the methods of conveying the electricity through rails or other conductors clumsy and unsatisfactory. In Mr. Reckenzaun's tramcars they had no stationary engine connected with it by a conductor, and this he considered, other things being equal, a very great advantage. After the experiments made by M. Philippart with tramcars propelled by a Faure battery, he was glad to hear Mr. Reckenzaun say that storage batteries had at last been made commercially useful and practical. He now believed the difficulties which had encountered secondary-battery makers in the past had been surmounted, and that the method of constructing them had been so enormously improved, that those who used them were now masters of the situation instead of *vice versa*. Pointing to the battery exhibited on the table, the speaker said every one was struck with its light weight, which was brought about by its being made of thin plates, thus giving a large surface and a greater current than had ever been found before in a secondary battery. This he considered one of the chief things they had to be thankful for, because this bringing within a small compass sufficient power to last for a few hours had been their stumbling block in the past. He had been informed that it was impossible to overcharge their batteries and that this could be done for months and months, but it is mentioned in this paper that this overcharging is detrimental to their working. The method of varying the speed and power devised by Mr. Reckenzaun is extremely ingenious and simple, avoiding the disadvantages of mechanical arrangements which would necessarily arise with numerous wheels, chains, or the like. As to the efficiency of electrically-propelled cars as compared with other means of locomotion, he thought that, although steam had made great progress of late years in the propulsion of tramcars, it still had very serious drawbacks, among which were that a small portable locomotive was far less economical than a stationary engine, especially as for the former they had to use a superior quality of fuel. Comparing the Scott-Moncrieff compressed-air car with the one then under discussion, professor Forbes remarked that it seemed to him that the arguments which applied to one applied to the other, and also pointed out that in Mr. Reckenzaun's car they saw for the first time the application of a worm-wheel to reduce the speed of the motor. In conclusion, he said it was satisfactory to hear that Mr. Reckenzaun was using electricity itself as a brake upon his car, because he thought that where electricity was applied as a motive power it ought also to be used as a brake power.

Mr. Traill (Giant's Causeway electric tramway) said that electric tramway engineers had a great battle to fight. They did not want to replace steam, but to aid railways and, at the same time, the outside public. He thought that through electricity underground railways would become things of the past. There was also the system of overhead tramways, such as was used in America, and which

Digitized by Google

the electric motive power was essentially fitted for, as it did away with the noise and dirt. There were four systems of utilizing the electric energy, and there was no doubt that the system carrying its own motive power, self-contained in its own car, had very great advantages indeed over any other system. The different systems were those which had overhead conductors, those which had side conductors, those which had underground conductors, and the system of accumulators. The overhead conductor was suited to very few places; then there was the side conductor, which they had adopted on the Giant's Causeway tramways. This system was very economical, and had many advantages, but after all was only applicable in very few places. There was the underground conductor which could be adapted to street tramways. The fourth system, viz., that of accumulators, had many advantages; indeed, it could be used on any line now worked by horses or steam. After repeated failures at the Giant's Causeway, they had at last hit upon a thoroughly reliable plan for getting the electricity from the conductor. This was by means of a steel spring in the form of a carriage spring, two concave steel springs fastened at the top and rubbing along the bottom.

Professor Forbes: "How long do they last?"

Mr. Traill replied that they had some running for nearly a year, and, when new, they only cost 5s. 6d. He was very much pleased with the system of Mr. Reckenzaun, and, having no doubt that it would come into very large use, he wished it every success.

Mr. Bernard Drake was of opinion that electric cars would have to be made smaller than those which had up to now been constructed in accordance with Mr. Reckenzaun's designs. He pointed out that not only would the smaller cars be more tractable in case of accident, but also that the question of stopping the car would not be so serious, as it stood to reason that if there were forty-six passengers on a car instead of twenty-three, the driver would be compelled to stop double the number of times in a given distance, and that the question of starting such a big car as now used was a severe strain. He considered that the arrangement adopted by Mr. Reckenzaun, of coupling the motors in series or parallel, or running a single motor, was both ingenious and practical; but as regards the overcharging of the extra cells, he thought that the question was more one of carrying the dead weights of these extra cells, which Mr. Reckenzaun had so ably explained was of the greatest importance in ascending gradients, than the mere destruction of the cells themselves. It was, of course, wasteful to expend your power in the evolution of gas after the cells were full, and would tend somewhat to soften the peroxide which might, therefore, be more liable to drop out when jolted by the car. He maintained, however, that the overcharging was not nearly as detrimental as was generally supposed. Mr. Drake drew attention to the large output per pound of lead obtained from the tramcar pattern of cell, and the general practical nature of the supporting of the plates and connections, and stated that, as manager engineer of the Storage company, he felt certain that the company was greatly indebted to Mr. Reckenzaun for the developing of the cells in connection with this class of work, inasmuch as numerous questions of detail had been found out by him, and that by these experiments a most valuable advance had been made in this class of accumulator. Referring to air cars, he thought there were very decided advantages in favor of the electric car, not only in weight, but also from the fact that the pressure of air began to fall from the moment the car came into use, for which mechanical arrangements had to be provided, and also the freezing caused by the expansion of air had to be faced, whereas in the electric car the E. M. F. is practically constant throughout the run, also the electric car would hold its charge for weeks together, whereas the air car charge would entirely leak away in a night.

Mr. Traill rose again and stated that his cars in Ireland have successfully traveled over 30,000 miles with 100,000 passengers, and that the electricity generated by water-power a mile distant costs one-quarter that of steam used on the same tramway. The commutator of the dynamo made 22,000,000 revolutions before it required repairing.

Mr. Shoolbred, M. I. C. E., said that he had seen Mr. Reckenzaun's car running on a difficult piece of line at Battersea, and he was struck with the simplicity of the system and the completeness of design in every detail. He thought that Mr. Reckenzaun's plan of varying the power and speed was just as applicable to a tramway having the current supplied through conductors as it is with accumulators.

Admiral Selwyn, in the course of some general remarks, said he hoped the Inventions exhibition would help the inventor to take his proper place in the country instead of being absorbed by the manufacturers, which was, after all, only one result of a defective patent law.

Mr. Waugh having spoken in encouraging terms of the prospects of electrical engineering, the chairman called upon Mr. Reckenzaun to reply.

Mr. Reckenzaun, in reply, testified to the great pleasure and instruction he had derived from the observations of professor Forbes, Mr. Traill, and the other speakers, and that he felt highly encouraged by the remarks of such authorities. He pointed out that the comparisons made by professor Forbes between compressed-air cars and electric cars do not hold good in all points, although there is a great similarity in principle. Compressed-air cars are much heavier, the weight of the air reservoirs under the car and its engine cannot be less than four or five tons if made to run eight or nine miles with a pressure of 500 lbs. to the square inch; the accumulators, motors, and gearing in the electric car weigh under two tons in order to propel the vehicle with forty-six passengers over a distance of 12 to 14 miles, and the time occupied in changing the cells at the end of the journey need not occupy more than three minutes. The moving parts in the mechanism of the air car, like those of the steam car, are at least five times in number as compared with the parts on the electric car, and this must be taken as a very great advantage. Moreover, the efficiency of the compressed air engine is lower than that of the accumulator and electric motor. Mr. Drake has very justly said that whilst the pressure in the air-car is gradually falling, the current of the electric battery is constant throughout, but as regards Mr. Drake's opinion that small cars may be more efficient than large ones, Mr. Reckenzaun remarked that a car capable of carrying only twenty-three passengers will weigh much more than half the weight of a 46-passenger car, and that if the traffic is sufficiently large, the bigger cars may be more economical. As regards the overcharging of the batteries, if some cells were used more than others of the same series, which would occur were the speed and power regulated by the number of cells, more stress should have been put in the text of the paper upon the fact that the energy wasted is more serious than the fact of sooner oxidizing the lead plates. Still, the object of the present system of regulation removes both these drawbacks.

THE PROPER METHOD OF OBTAINING THE AVERAGE DURATION OF AN INCANDESCENT LAMP.[1]

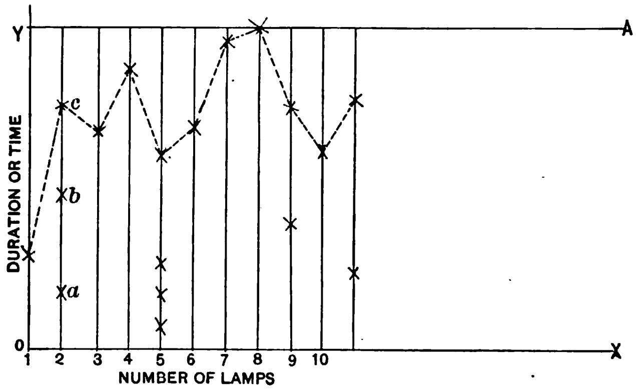
BY J. A. FLEMING, M. A., D. SC.

Recent statements on the average life of incandescent lamps and other general practice agree in indicating a certain absence of clearness in many minds on the proper principles by which the desired average quantity can be obtained from the experience of observations. It seems desirable, therefore, to call attention to the proper method by which alone any figures at all useful can be obtained. To do this we shall adopt, what is always best when possi-

1. The *Electrician* (London).

Digitized by Google

ble, graphic illustrations instead of symbols. Let us suppose that there is an incandescent lighting plant set up for continuous or intermittent use, and that the person in charge desires to arrive at some correct notion as to what is the mean duration of the carbon filament under any condition of working. On a line, o x, mark off equidistant



points, each one of which represents a working lamp. Draw vertical lines through these to represent time or duration, and the crosses represent the time or dates at which lamps are replaced. Thus in the diagram, lamp 2 is replaced at three periods, represented by the crosses *a*, *b*, *c*; the first lamp burnt for a time 2*a*, the second for a time *a b*, the third for a time *b c*, and the fourth lamp is yet burning.

Now, suppose that a trial period of time is taken, represented by the distance between the horizontal lines through A and X. The distance A X represents the duration of this trial run. Supposed it is desired to obtain the average life of the lamps during this period, then the *usual* mode of arriving at this quantity would be to divide the total lamp hours by the number of replaceals, and deduce (perhaps to a decimal) the average life of the lamp. If matters could be so managed that if the lamps all gave out at once, and that the trial run finished exactly with the expiry of all lamps, it is obvious that the above mode of procedure would be correct; also if the lamp hours of every separate lamp were taken from the beginning of the trial up to the end of the duration of a life, the same having been replaced 1, 2, 3 or *n* times. Then it is also obvious that the average life would be the average of the average deduced by dividing the whole lamp hours of *each* lamp separately by the number of times that lamp has been replaced. But neither of these two processes is practicable in a general way, and accordingly we can deduce no accurate average from any trial in which there remain at the end of the trial unexhausted lives, or lamps which have in them yet lamp hours of potential working. Referring once more to the diagram above, we see that the diagram may be divided into two parts, one above the dotted line formed by joining all the last crosses and one below. The united lengths of all the vertical lives included between the dotted line and the horizontal O X represent the lamp hours of burnt out lamps. The united lengths of all the parts of vertical lines between the dotted line and the upper horizontal, A Y, represent the lamp hours burnt by lamps yet alive and likely to live.

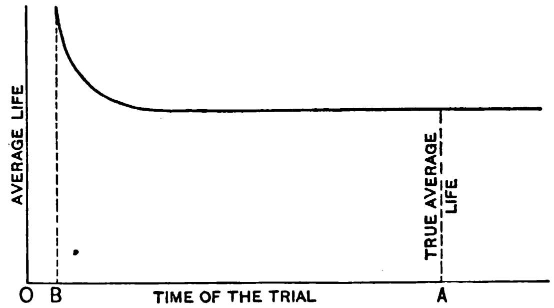
Now let us call these two parts the total exhausted lives, and the total unexhausted lives.

If the lamp hours of unexhausted lives form an appreciable or moderate fraction of (much more if it exceeds) the lamp hours of exhausted lives, then the application of the common rule only leads to ridiculous results. And the only circumstances under which the quotient of total lamp hours by replaceals gives a correct approximation to the average life is when the total unexhausted lamp hours is small or negligible in comparison with the total exhausted lamp hours. And under the former supposition the average life is always overestimated. Accordingly, the moral of this is, no trial tests or experimental runs are of the least use for the purpose of averaging the life of incandescent lamps which do not last for a period at least four or five times the average duration of a lamp, that is for 5,000 or 6,000 hours, and the longer the better.

If a given number of lamps be set up and run continuously, and replaced as they fail, and the ordinary rule applied at stated intervals, it would be found that as the trial run extends in time, the average life deduced would diminish towards a fixed minimum, which is the real average.

It is easily seen that the ordinary rule makes the average life of a lamp infinite for short trials, which, as Euclid would have observed, "is absurd."

If we plot down the results of applying the common rule as ordinates along a scale of time representing the time of the trial, then it is easily seen that for time zero, life is infinite; and as the time of the trial increases, we eliminate more and more the respective proportion of unexhausted lives as compared with total lamp hours of exhausted lives, and approximate to a horizontal position in the life curve, which gives the true average life by its distance above the horizontal line. These considerations if weighed will, it is so to be hoped, prevent those in charge of installations from rushing into print with statistics derived from one or two hundred hours of burning. Although, as the results of



such too limited experience will always be to bring out the average life of the lamp too high, it is, perhaps, hardly likely that lamp manufacturers will refrain from quoting them in their own favor, or come forward to instruct the publisher of them in the true principles which should control the collection of observations intended to furnish an approximate estimate of the mean duration of incandescent lamps properly used.

One further remark suggests itself in connection with the statistics which have given rise to discussion on this subject, and it is this, the vital importance of working all lamps at the proper E. M. F. necessary to make the expenditure of energy in them equal to the proper watt mark of the lamp. And knowing as we do what serious variation is made in the average life by a difference of one or two volts (considered by many of small importance), it is obvious that the careful and systematic use of known accurate voltmeters should be a matter of consideration with every one who has the care of incandescent lighting.

RIVER CROSSINGS IN COCHIN CHINA.

The longest spans of overhead telegraph wire in the world have recently been put up by the French authorities in Cochin China. These are erected across the river Mekong, posts 160 feet high having been placed on each side of the river at a spot where the width is 2,560 feet; and from these silicious bronze wires—one .04 of an inch and the other .055 of an inch in diameter—are suspended across the stream. Over a tributary of the river another similar connection has been made 1,670 feet span and more than 114 feet above flood water.

DYNAMOMETERS.[1]

BY C. F. WHITE,

Member of the Engineers' Club of St. Louis.

POWER measurement has been carried on ever since prime movers have been employed, and the great variety of devices for such measurement are but different forms of dynamometers..

The friction-brake and the indicator represent two classes of power measuring machines in very general use. But the word dynamometer is acquiring a narrower and more technical meaning, so that at present it most often means a machine for transmitting and, at the same time, measuring power. Hence the full name, transmitting dynamometer.

The demand for this class of instruments has increased with the movement toward centralization in development

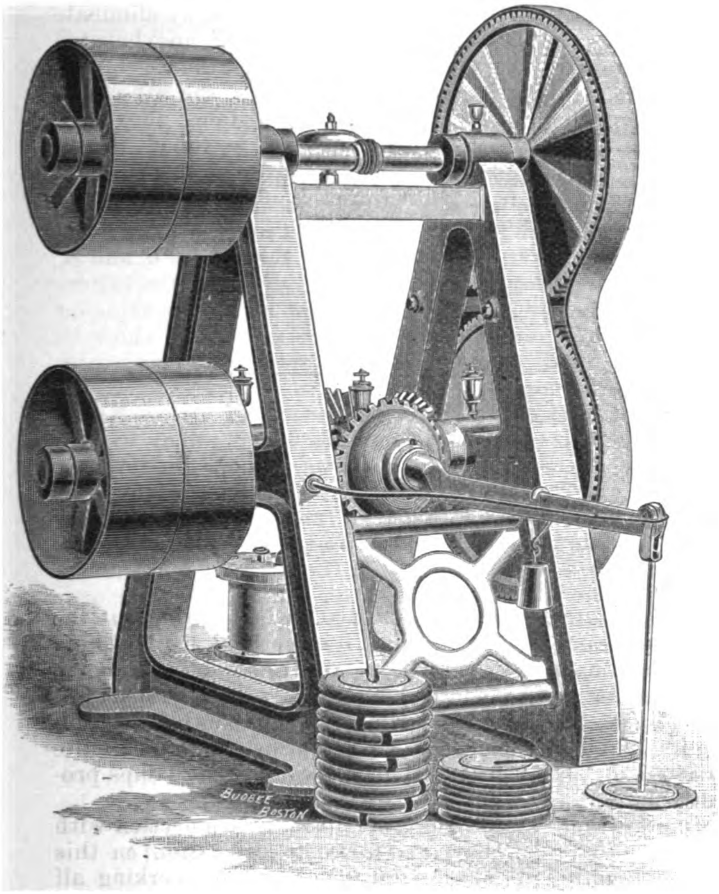

FIGURE 1.

of power, and also with the growing call for a more exact knowledge of the power required for various kinds of work. Members of our club have informed us of the excellent appliances at hand for the measurement of gas and of water, and I am glad to call your attention to several recent forms of power-meters, fully equal, I believe, in convenience and accuracy to gas or water meters.

Right here I ought to say that most of the dynamometers which I shall mention have been described at different times in technical and engineering journals. A short review of their leading features will not, I believe, be amiss.

In a transmitting dynamometer some element of a train of mechanism is deviated from its normal position by the force transmitted. This deviation is resisted and measured by weights or by springs.

If three gear-wheels be run together, there is an effort exerted on the axis of the intermediate one, tending to move it out of position.

When power is transmitted by a pulley, the arms bend more or less from their original shape.

One part of a belt is tightened, and another part relaxed, by the transmission of power through it.

In that form of transmitting dynamometer devised by Wm. Kent, M. E., the shaft carrying the intermediate gears is arranged as a pendulum, and in its normal position hangs vertically. The force transmitted through the box-mitre-gears swings this pendulum from the vertical. This swing movement causes a pencil to traverse a paper drum having a motion at right angles with the pendulum plane, and proportional to the speed of the gear-wheels. A suitable clock-work marks equal intervals of time on the paper. From the diagram thus produced, the intensity of the force and the distance through which it has acted may be read and the power determined.

The "improved balance dynamometer,"[2] figure 1, also uses as the deviating element box-mitre-gears. A double-letter "A" frame carries across its top a shaft on which, at one end, is a large spur-wheel, at the other tight and loose pulleys. Across the centre-bars of the frame extend the two gear-shafts, one of which has a spur-gear, and the other tight and loose pulleys exactly like the upper shaft. The arm carrying the intermediate mitre-gears is prolonged into a scale-beam. The tendency of this beam to rotate, when transmitting power, is overcome by weights hung to it. A small gong is struck at the end of each hundred revolutions of the shafts. The scale weights are so stamped that by dividing the number on them by the number of seconds to each hundred revolutions times the equivalent of a h. p. in foot-pounds per second, the h. p. transmitted is obtained:

$$\frac{\text{Stamp.}}{\text{Seconds to 100 rev.} \times 550} = \text{H. P.}$$

Mechanism for giving a continuous record may be used, if desirable.

The apparatus brought out by Hamilton Ruddick,[3] figures 2 and 3, consists of a sleeve secured to the shafting carrying on opposite sides radial arms. Loose upon this sleeve is a pulley having a pair of arms similar to those just mentioned. Between the ends of these arms springs are placed, which are compressed proportionally to the force transmitted from shaft to pulley, or vice versa. A pencil arm, pivoted on the sleeve and connected with the pulley by a link, moves, with the compression of the springs, across the face of a flat paper disc; and by its distance from the zero line indicates the intensity of the force transmitted. Motion of rotation is given to the disc by means of a differential gearing, actuated by a ratchet and a stud, which, projecting through the rim of the pulley, is moved once at each revo-

lution by the belt pressure. By a suitable adjustment of the gears, the disc may be made to revolve in any desired period of time, and from the distance through which the disc has moved a record of the number of revolutions is had.

Another transmitting dynamometer,[4] designed by F. Van Winkle, figure 4, has been recently put upon the market. A strong cast-iron plate is strapped to the arms of the transmitting pulley, the pulley being loosened upon the shaft. A second plate with a long hub is placed near the first, centred about and secured to the shaft by set screws. A pair of tension springs transmit the motion of one plate to the other, and are elongated in proportion to the load. The movement of the plates past each other becomes the

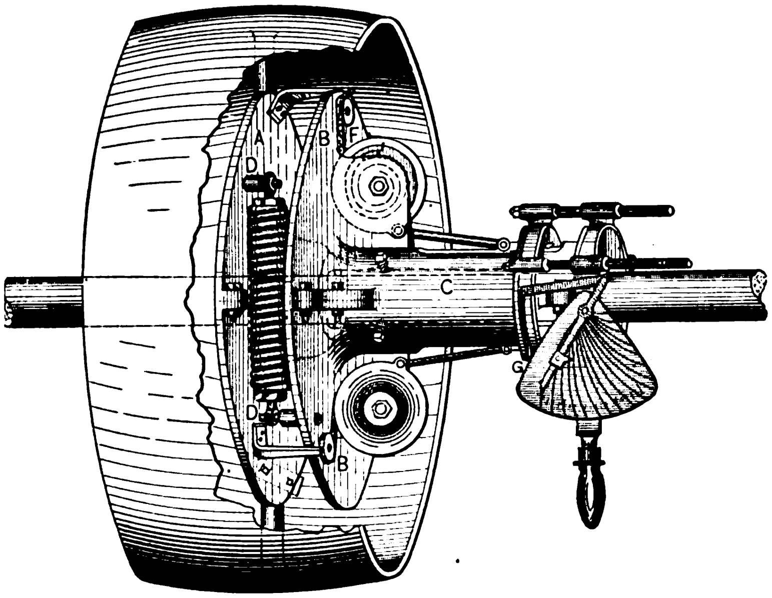

FIGURE 4.

measure of the transmitted force, and by means of a steel ribbon and suitable pulleys causes the hand on a stationary dial plate hanging from the long hub to move. The machine is so adjusted that, the diameter of the pulley and the number of revolutions being known, the h. p. is read off at once. Continuous record attachments are also made for the instrument.

The "Emerson power scale"[5] is a rotary transmitting dynamometer, by which the load is weighed with weights and levers, as in a common scale. A circular frame, or "spider," with a long hub, is secured to the shaft close up to the driving pulley. Around this spider is a rim free to rotate, and from which studs project and serve to connect it to the pulley. In transmitting power from the shaft to the (loosened) pulley, the tendency of the rim to rotate on the spider is resisted by a system of levers which communicate with a pendulum balance weight.

As the system of levers receives the transmitted force at a known distance from the centre of rotation, the distance traversed per revolution is known. A speed counter shows the revolutions, so that the force indicated by the pendulum times the number of revolutions per minute times the constant, divided by 33,000, is the h. p.

$$\frac{\text{Reading of scale} \times \text{rev. per minute} \times \text{constant}}{33{,}000.} = \text{the H. P.}$$

In reviewing briefly the machines described, the Kent and the Lawrence dynamometers form a class by themselves, as both are independent apparatus requiring setting up and special belting. Each machine is capable of being adjusted to do all that the other will do.

Of the three rotary dynamometers, the Ruddick stands somewhat alone, from the facts that it must replace the usual driving pulley and readings can be taken only when at rest. It is, however, very compact, and furnishes a convenient record sheet from which both force and distance can easily be read.

The Van Winkle and Emerson machines have in common certain features which recommend them highly for some classes of work. Both are so made (split) that they can be put on a shaft alongside the regular pulley without disturbing pulley or belt, save loosening the set screws. The dial plates hang quietly from the shaft, and the power may be read off at any moment.

In all of the dynamometers which we have just noticed, the record is made in a direct ratio to the force transmitted, and upon a scale not readily changed.

By the kindness of a friend, I am able to present to you to-night the details of a new transmitting dynamometer which have not before been brought before the engineering public. The apparatus has a number of interesting features, and I ask your attention to its construction, the theory on which it is based, and to its performance under severest tests.

This new dynamometer, which is sold under the name of Wales's portable dynamometer,[6] makes use of the difference in tension in the two parts of a belt transmitting power, figure 5. Two rolling pulleys, AA, swing upon pivots, CC, which are supported in castings, DD. The castings slide upon the bar E, so that by means of the chain F and the winding drum G the pulleys AA may be drawn together, causing the belt to contain the angles θ and β. These angles, being made equal in adjusting the instruments, the tension of the belt when at rest is the same on either side, and causes equal pressure on each of the rolling pulleys, tending to force them apart, but being prevented from doing so by the tie-rod O.

When motion occurs in the direction of arrow No. 1, any transmission of power from the lower pulley to the upper one causes an increase in tension along the "upper side" of the belt, and a decrease of tension along the "lower side." The difference of tension thus caused between the two parts of the belt forces the rolling pulleys and the tie-rod O to swing about the points C C in the direction of arrow No. 2. The latter action causes the arm H to move out of parallelism with the arm I, to which is fixed the bracket N. This movement extends the spring L until its resistance counteracts the pressure on AA, due to difference of belt tension. The movement of the arm H causes the pencil X to move outward upon the paper drum J. The latter is given a motion of rotation by means of a train of differential gearing, M, driven from the arbor of one rolling pulley. The combined motions of the pencil and the paper result in the tracing of a line, the height of which represents the force transmitted by the belt, and the length of which represents the length of belt passing over the rolling pulley during the time of the experiment. An inch of height of this pencil line will represent different amounts of belt tension, according to the value of the angles θ and β, and also according to the distance from C of the spring L, the spring being arranged to slide to four positions along the arms H and I. Consequently, by a proper selection of value for the belt angle and for the position of the spring, the pencil can be made to move through its maximum height for any amount of power measured. The following table exhibits the range of the instrument for various values of belt angle and position of the spring.

The table gives the h. p. represented by one inch height (or rise) of pencil line per 1,000 feet of belt travel per minute.

The figures in the first column are readings of an angle-gauge supplied with the instrument, and specially adapted to the measurement of the belt angle. The gauge is shown in the cut at *a d c* applied to the belt.

The graduations are made to represent the ratio of the tension along the belt, to the component of this tension acting along the line joining the centres of the rolling pulleys.

Directions for using are engraved upon it.

Measurement of belt speed is had in two ways:

1. By timing the revolutions of the primary gear-wheel. The primary wheel of the train giving motion to the paper drum is graduated to serve as a speed counter, each revolution of the wheel representing 100 revolutions of the rolling pulley. The circumference of the latter, for single belting, is exactly two feet. Hence each revolution of the primary gear-wheel represents 200 feet of belt-travel.

2. By measuring the length of the diagram. The differential gearing is so arranged that 1,250,000 revolutions of the rolling pulley cause one turn of the paper drum. The latter is $12\frac{1}{2}$ inches in circumference; consequently, each inch of length of a diagram measured parallel to the base-line represents 20,000 feet of belt travel.

The expiration of each minute is recorded on the diagram by a telegraph sounder carrying a pencil which bears on the paper, and which is caused to make a stroke once a minute by the passage through a mercury cup of the hand of a minute clock placed in battery circuit leading to the sounder.

An inspection of the table of h. p. shows the extraordinary range of the instrument. It will be seen that the scale of the diagram may be varied so that an inch of pencil motion may represent ninety-four one-thousandths of a h. p., or ten times this amount at 1,000 feet per minute belt speed. The maximum rise of the pencil is five inches. Hence, at the same belt speed, five inches of pencil motion could be produced by forty-seven hundredths of a h. p. with a belt angle of about 120 degrees, and the spring close to the rolling pulley; or five inches rise could control forty-five and four-tenths h. p. with a flat belt angle, and the spring at its farthest position on the arm H.

At electric light belt speed of 4,000 feet per minute, five inches of pencil motion would control 30 h. p. with the spring at position one and a moderate belt angle; while with the spring at four, about half a h. p. would move the pencil an inch. So that the full power of a 30-light dynamo on the one hand, or the power needed to merely overcome the friction of its journals on the other, could be recorded on a sufficiently magnified scale to insure accuracy.

This extraordinary range of capacity is due in a measure to the influence of the belt angles, but the principal cause is found in the fact that the movement of the spring affects the pencil scale as the *square of the distance* of the spring from the centre of the rolling pulleys. This will become apparent from a consideration of the appended statement of the theory of the instrument.

Let T = tension of the belt when at rest.

" ΔT = increase of tension on "upper side" = the decrease on the "lower side;" whence the resultant pressures upon the rolling pulleys are:

$2\ (T + \Delta\ T)\ \cos.\ \frac{\theta}{2}$ for "upper side" acting in the direction $f\ B$ bisecting θ.

$2\ (T - \Delta\ T)\ \cos.\ \frac{\beta}{2}$ for "lower side," acting in the direction $b\ R$, bisecting β.

Digitized by Google

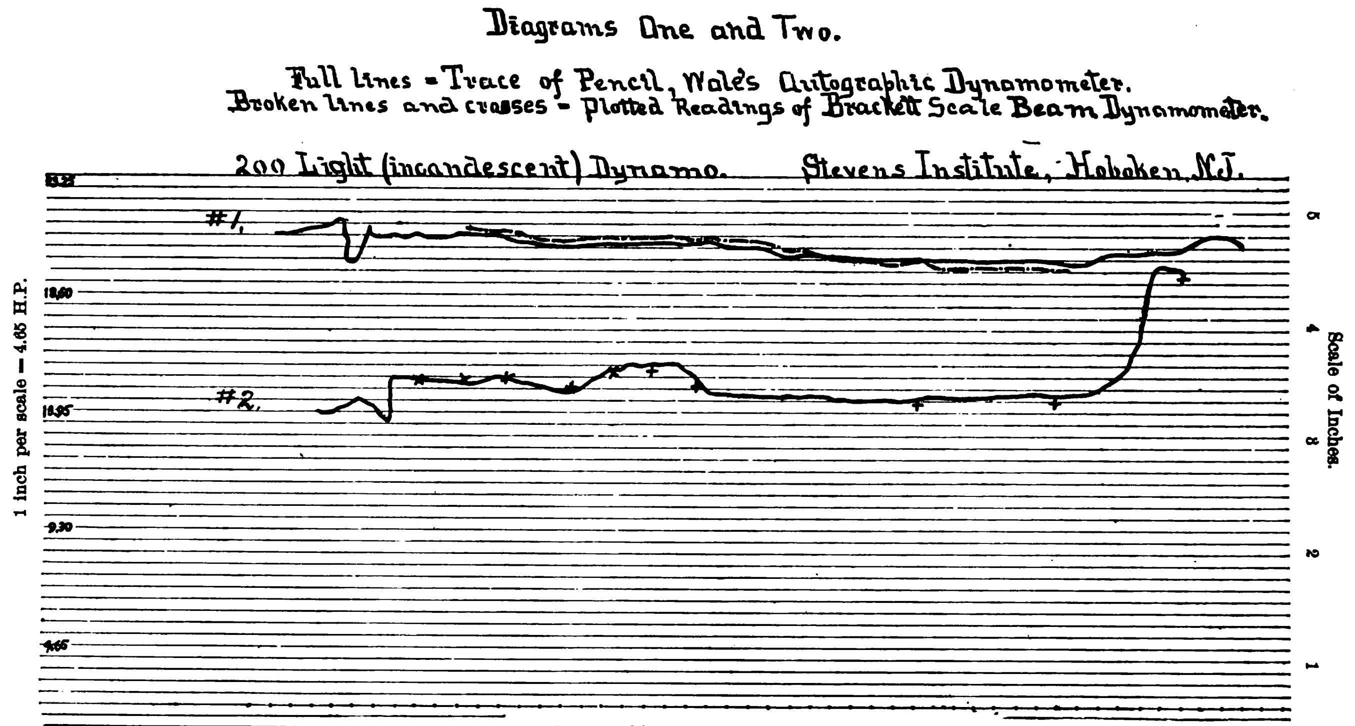
If α be the angle between the tie-rod (o) and the bisecting lines $f\,B$ and $b\,R$, then the above pressures resolved along the direction of the tie-rod are :

$\left[2\,(T + \Delta\,T)\cos.\frac{\theta}{2}\right]\cos.\,\alpha$ for "upper side" in direction $o\,B$.

$\left[2\,(T - \Delta\,T)\cos.\frac{\beta}{2}\right]\cos.\,\alpha$ for "lower side" in direction $o\,R$.

The difference between these two pressures is, putting $\theta = \beta$, $4\,\Delta\,T\cos.\frac{\beta}{2}\cos.\,\alpha$ acting in the direction of arrow No. 2, and it is this amount of force which causes the rolling pulleys and the tie-rod to swing about ($C\,C$) and extend the spring. The angle gauge is made and graduated so that if applied with the arms a along the belt and with the moment about C of this resistance will be $X\left(S.\frac{X}{L}.\frac{h}{\rho}\right)$ inch-pounds, which must equal the moment $l\;(2\;A\;\Delta\;T)$ inch-pounds. Or we have : $X\left(S.\frac{X}{L}.\frac{h}{\rho}\right) = l\,(2\,A\,\Delta\,T)$; whence the difference of tension represented by any height of the pencil, as h, is $2\,\Delta\,T = \frac{S\,X^2\,h}{A\,l\,L\,\rho}$ pounds.

The power transmitted will be, the belt travel times the difference of tension, or if $B =$ the belt travel in feet per minute, then the power in foot-pounds $= 2\;\Delta\;T\;B$. The h.p. $= \frac{2\,\Delta\,T\,B}{33{,}000} = \frac{B\,.\,S\,.\,X^2\,h}{A\,l\,L\,\rho.\,33{,}000}$, or per one inch rise of pencil, the h.p. $= \frac{B\,.\,S\,.\,X^2}{A\,l\,L\;33{,}000}$, or a constant times $\frac{B\;S\;X^2}{A}$



Autographic record of minutes made by Electric Register. Each dot marks the expiration of one minute = 3,850 ft. of belt speed.

the graduated plate so held that its straight edge is parallel to the tie-rod, the reading is equal to $2\cos.\frac{\beta}{2}\cos.\,\alpha$.

Let this be represented by A. Then we have that $2\;A\;\Delta\;T$ equals the force acting in the direction of arrow No. 2. But, $2\;\Delta\;T$ equals the difference of the tensions on the two sides of the belt ; hence the reading of the angle gauge is the ratio of the difference of belt tensions, to the component of this difference acting along the line joining the centres of the rolling pulleys.

We have, that the moment of $2\;A\;\Delta\;T$ about c must equal the moment of the resistance of the spring about c.

To obtain the latter, let—

$S =$ scale of the spring, or load in pounds required to extend it one inch.

$l = C\,R = C.\,\beta\,B =$ lever arm of the force $2\;A\;\Delta\;T$ about c.

$X = C\,N =$ lever arm of the spring about c.

$L = C\,H =$ lever arm of primary point H of the pencil motion.

$\rho =$ ratio of movement of H to movement of pencil point.

Then for h inches rise of the pencil the point H will move $\frac{h}{\rho}$ inches, and hence the spring will extend $\frac{X}{L}.\frac{h}{\rho}$ nches, whence the resistance will be $S.\frac{X}{L}.\frac{h}{\rho}$ pounds, and

And it is the value of this constant which is given in the table, B being expressed in thousands of feet. It is evident that the scale of the diagram varies as the *square* of the distance of the spring from C, and this fact is the principal cause of the great range of the instrument, which is such as to render the power transmitted per unit of weight of apparatus greater than any form of dynamometer yet devised.

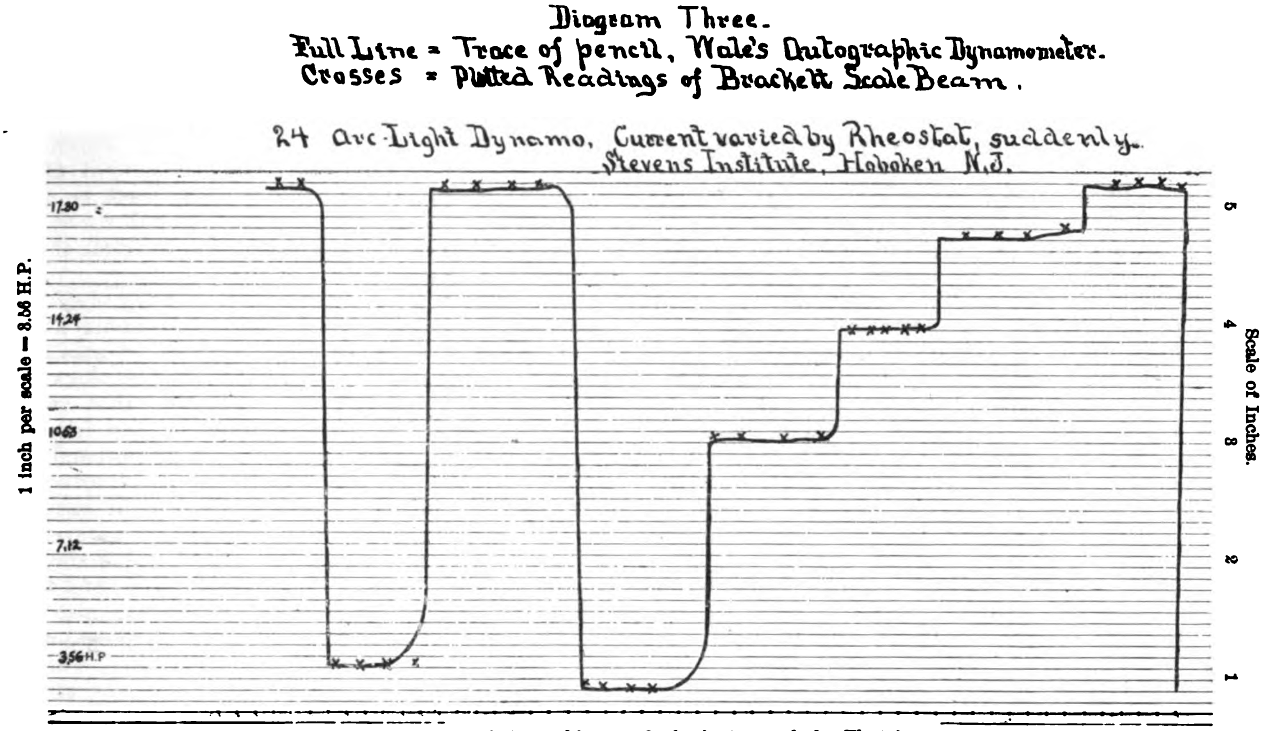
TEST OF ACCURACY OF WALES'S DYNAMOMETER.

The following rigorous test of the instrument was made in the Department of Experimental Mechanics, Stevens Institute of Technology, Hoboken, N. J. :

The dynamometer was arranged upon a vertical belt, driving a large dynamo on the floor above. The dynamo was supported by an iron **U**-shaped cradle, hung upon knife-edges. Steel plates on wooden frames carried the latter. The axis of the dynamo-shaft and the bearings of the knife-edges we adjusted so as to be precisely in the same horizontal line. Thus the cradle and the contents were entirely free to oscillate about the axial line, and being delicately counterpoised, the centre of gravity of the entire mass was brought nearly into this axial line. Under these conditions a very slight force applied to the dynamo on a line *not* passing through the axis, as at the circumference of the driving pulley, would cause a sensible vibration of the

Digitized by Google

scale beam attached to the cradle, so that by applying weights to this beam the force exerted by the belt could be accurately weighed. The driving force being thus determined, the h.p. expended at the dynamo became known by observing the rotative speed of the spindle. This was measured by a speed counter attached to the spindle, and so manipulated that the revolutions were determined within one-third of one per cent.



Autographic record of minutes made by Electric Register. Each dot marks the expiration of one minute = 3,560 ft. of belt speed.

This method of weighing the power of a dynamo, which has been brought into prominence by Prof. Brackett, of Princeton College, is evidently as nearly perfect as practice can realize, for with properly designed knife-edges and careful balancing, the arrangement possesses all the accurate qualities of the steelyard, and must be regarded as the very basis of power measurement.

In the case of the apparatus at the Stevens Institute, a dynamo weighing 3,000 lbs. was so balanced that a weight of 3 oz. (.1875 lb.) at ten inches from the spindle would cause the beam to vibrate through one inch at the index. When it is added that the absorbent of the power was a dynamo running through a rheostat adjustable in its resistance to the one hundreth of a h.p., and as steady as possible, it becomes apparent that the test conditions are as crucial as a dynamometer can be placed under.

Three tests were made, two with a 200 incandescent light dynamo, and one with a 24 arc-light machine.

In the first case, the current from the dynamo was varied miscellaneously, by the fluctuation of resistance due to the switching in and out of lamps, etc.

In the second case, frequent and considerable alterations of current were made by the rheostat in order to show the degree of promptness with which the autographic instrument would respond to sudden changes of power.

Diagrams 1 and 2 show the resulting autographic records in the first case, and diagram No. 3 the records of the second case. The full lines of these diagrams are fac-similes of the actual pencil trace; the vibration of the pencil, usually so inseparable from the automatic registration of power, having been overcome by using a flexible brass wire, T, for a tracer. The point of the wire pressed upon chemical paper with sufficient friction to cause the vibrations to expend themselves in the flexure of the wire without displacing the point, while permanent movements of the wire were immediately responded to by a movement of the tracing point.

In the diagrams the crosses and broken lines are plotted observations from the Brackett dynamometer.

CARRYING AND DISTRIBUTING ELECTRICAL CONDUCTORS THROUGH CITIES.

BY ELIAS E. RIES.

How to bury the present network of overhead wires in the quickest and most economical manner and with the least disturbance of the public streets, is a question which has lately been much agitated in some of our larger cities, and a number of plans have been proposed for accomplishing this end. In most cases, however, the principal thing to be taken into account in this connection has been overlooked, and that is the probable future growth in the demand for electrical service of various kinds.

It is apparent that when the present rapid increase in the local demand for electrical service is considered and when it is remembered that the various applications of electricity in their adaptation to different forms of public service are as yet comparatively undeveloped, and that the present tendency in electrical progress and practical development is in the direction of a house-to-house supply or service, the question of properly carrying and distributing the large number of conductors that will be required to supply this demand is one of vital importance, and a conduit system that does not provide for the future needs of the city in this respect will be open to very serious objection.

It is very evident that if the city streets, already overcrowded with a subterranean network of gas and water pipes, sewers and in some of the larger cities, with cable railway conduits, steam pipes for supplying heat and power, pneumatic tubes, etc., not to speak of the experimental electric conduits already laid, are given over to the various present and prospective electrical companies, they will soon become so cut up by the conduits and the distributing and service

Digitized by Google

tubes of the different companies (granting for a moment that all the conductors can be satisfactorily and economically operated when so buried), that the streets will not only become so overcrowded and interwoven with the various underground service systems that the limit of capacity to further construction will soon be reached, but the constant tearing up of the streets for making the repairs, connections and alterations necessary in such a complicated subterranean network will cause such serious interruption and annoyance that the thoroughfares will ultimately become entirely unfit for traffic. Not only will the future growth be large from natural causes but it must be remembered that rival electrical corporations will be sure to spring up to claim a share of the public patronage as soon as the privileges and patent rights controlled by the present telephone, lighting, power, heating and other electrical companies have expired, as has heretofore been so often demonstrated in the case of gas and telegraph companies.

It is clear, then, that the only satisfactory means of attaining the required object would be by means of a single general underground conduit system designed and adapted to carry and properly distribute all electrical conductors that may be necessary. We will therefore briefly consider the requirements that are essential in a conduit system of this kind, which may be divided into two classes—practical and technical.

The practical requirements are: first, a perfect system of main, branch and distributing conduits or subways capable of supplying every portion of the city with such conductors as it may require; second, ample capacity for receiving and distributing electrical conductors of every kind that may be necessary for all present and future needs; third, suitable facilities for making repairs and connections, and for laying additional conductors without in any manner disturbing the streets or interfering with traffic; fourth, facilities for permitting thorough personal inspection of the entire interior of the main and branch conduits; fifth, economy in construction, operation and maintenance of the conduit system; sixth, comparative non-interference with traffic during the building or construction of the conduit.

The technical requirements are: first, suitable interior arrangements whereby conductors of different classes may be carried without interfering with one another; second, means for preventing leakage and induction between the various conductors of the conduit; third, means for preventing or overcoming the effects of retardation. Let us now see if these requirements can be carried out in practice.

As we have seen, to permit the different electrical companies to indiscriminately bury their wires to suit their own ideas would be extremely hazardous and will sooner or later prove seriously detrimental to the interest of the cities. The number of complete conduit systems that a city can accommodate is very limited, and if it is possible to build a single conduit system with sufficient capacity for all present and future needs it will be decidedly more preferable in every way, even though the first cost is slightly more, than to build a separate system at some future time, or to build two or more independent systems as has been suggested, for conductors of different kinds, and will save the unnecessary digging up of a great many streets.

Among the requirements necessary for a conduit system such as we have under consideration, are first, sufficient capacity to receive and carry all electrical conductors that may be required, and second, ample facilities for readily and systematically distributing these conductors, so that every part of the city may be promptly and thoroughly served with any desired class of conductors. The conduit system, moreover, must be so arranged that a wire may be carried from any one point in the city to any other point, no matter how distant or where located, *with the least possible deviation from a direct line*, and it must also provide as well for the proper distribution of conductors intended for district supply purposes.

Now, laying aside the technical difficulties that will have to be overcome in any underground conduit system, it is clear that to build a complete system of underground ways or conduits which will meet these requirements and be large enough to properly accommodate all the necessary conductors and permit of ready access for inspection, repairs, etc., is, in any of our large American cities, a practical impossibility, on account of the large number of underground works that already occupy in the most inextricable confusion all of the most available thoroughfares, and to remove and reorganize which, if not absolutely impossible at the present time, will at least be attended with such an enormous expense, and would result in such serious inconvenience and interruption to traffic that it will scarcely be attempted.

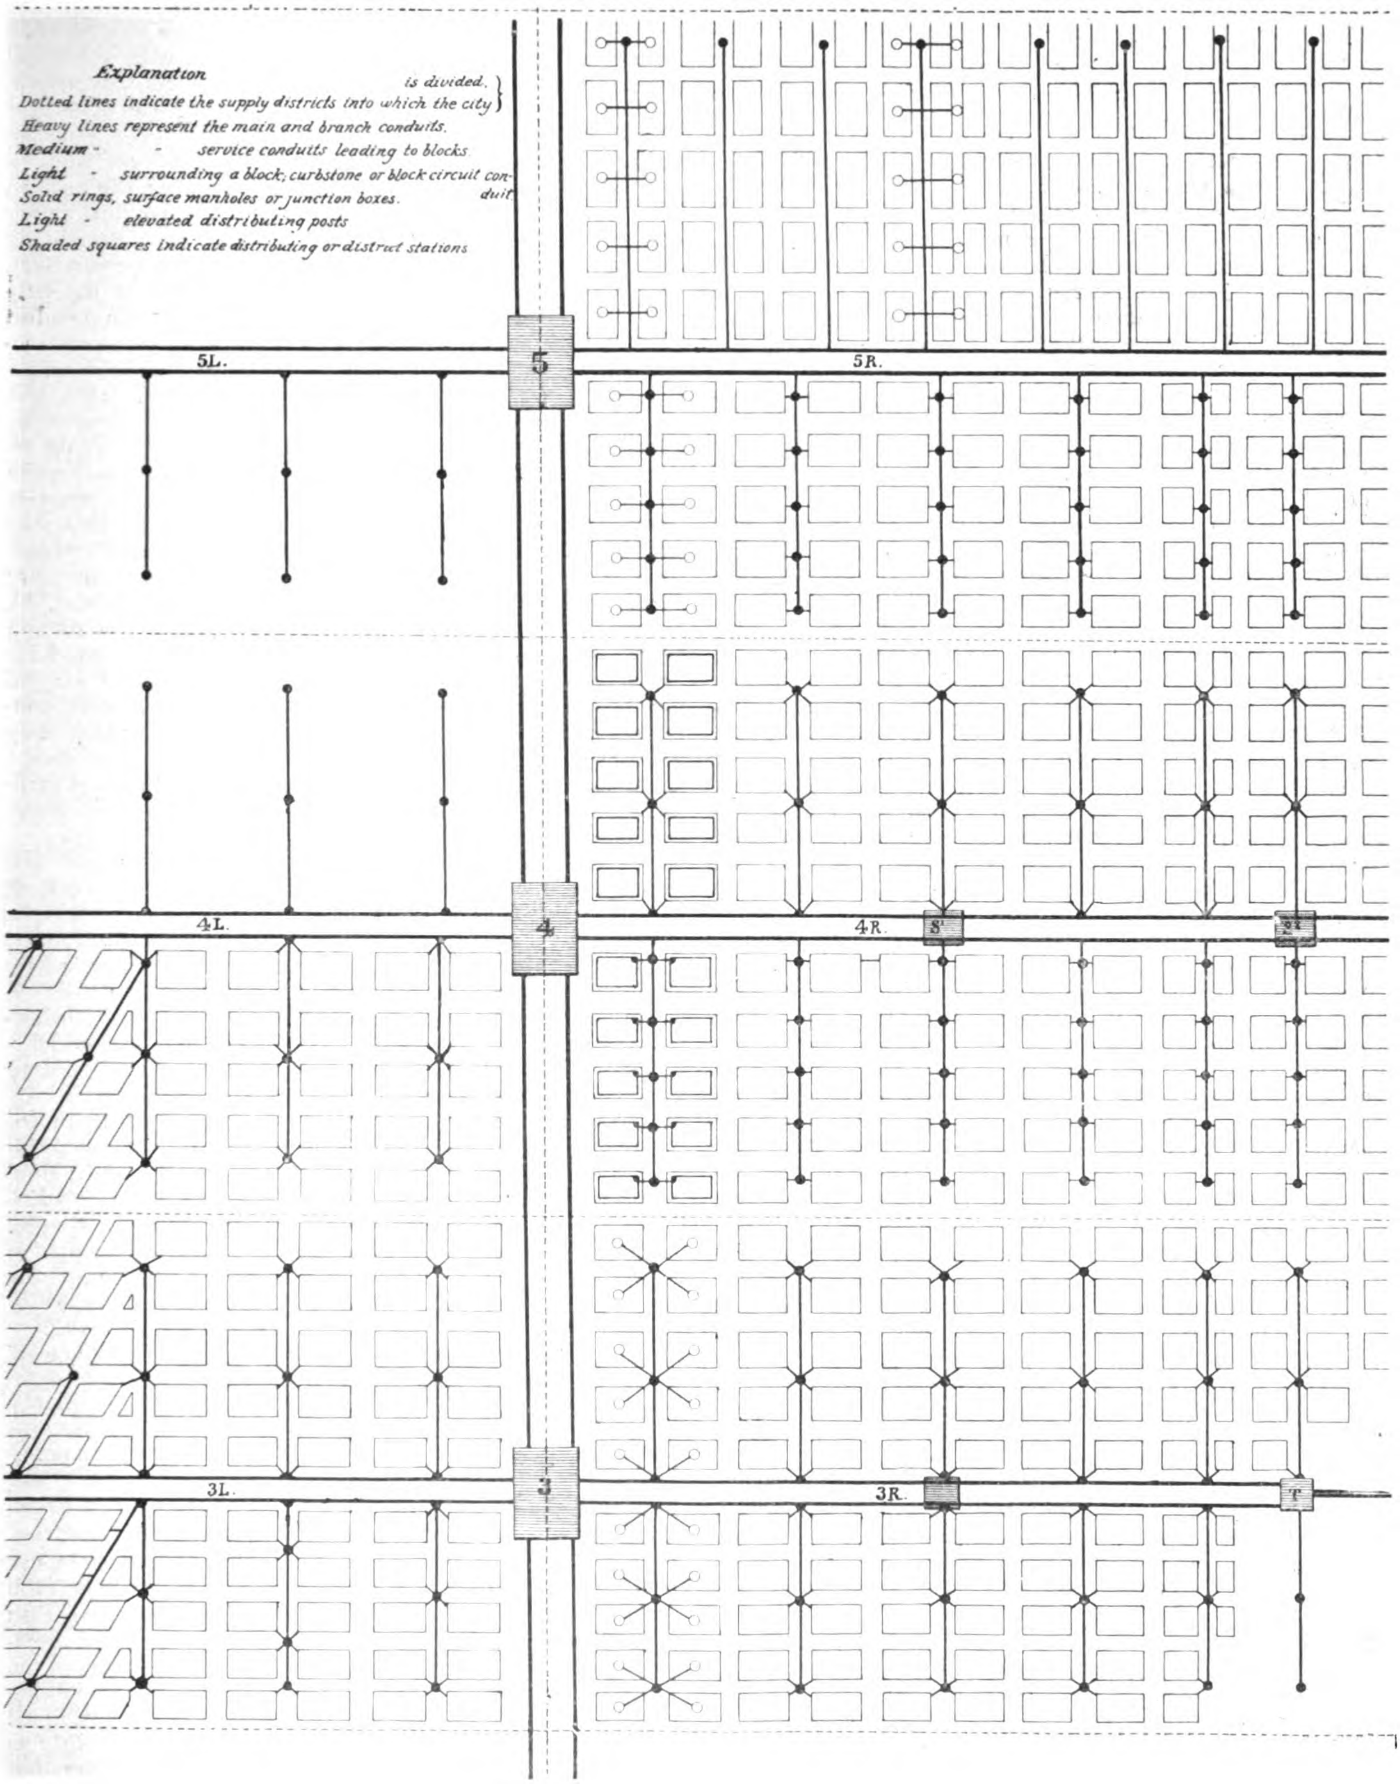
It will be seen then, that we have a very obstinate and practically insurmountable difficulty to contend with. On the one hand, if we run a large number of small subterranean conduits in every direction through the streets of our cities we only add to the confusion that at present exists in underground service systems, and increase the difficulty of laying additional tubes, pipes or conduits. On the other hand, if we attempt to construct a limited number of subways large enough to accommodate at once all the electrical conductors required, we are met at every point by the firm and immovable water and gas mains, sewers and similar obstructions. In projected cities and towns an underground system of subways, which can also be used for ordinary city service and supply purposes, can very readily be built if the money is forthcoming, which however it seldom is, while in populated cities the streets are already so occupied by the necessary drainage supply and service systems that the construction of a properly organized system of subways is practically impossible.

However, there is a simple and very effective method of overcoming this difficulty despite the obstacles that oppose the satisfactory and economical construction of an underground system. This consists in compromising upon a system of overhead or elevated main and branch ways, and underground distributing and service conduits, and it is proposed to show that this system if properly carried out, has several important advantages over any possible system of underground conduits, both from a technical and practical standpoint, and that by means of this system it is possible to overcome some of the principal difficulties heretofore encountered in operating underground conductors. It may be remarked here, however, that the system or plan of distribution about to be described is equally well adapted for a complete underground conduit system, provided the construction of such a system can be successfully carried out despite the difficulties already mentioned as opposing it.

This system comprises a main *elevated* conduit structure or way running along one of the streets or avenues, in the direction of the city's length, if the length of the city should greatly exceed its breadth, or in the prevailing direction now taken by the wires. The street or avenue selected for the main conduit structure should be if possible, in the approximate centre of the city, and run as near as practicable in a straight line throughout its entire length. This main structure is supported by a double line of tubular iron posts, somewhat in the manner of the New York elevated railways, and the superstructure or way that is intended to support and carry the electric conductors covers the entire central portion of the street or avenue, leaving the sidewalks and a portion of the street on either side uncovered.

This elevated roadway is divided through its entire length into five longitudinal parts, the object of which will be considered later. The two portions on either side of the central division are set aside for the electrical conduits, of which there are two, one for the electric light and power conductors, etc., the other for the telegraph and telephone conductors. Each of these conduits, which are completely enclosed, has a central passage extending through its entire length, said passage being large and high enough to readily

Digitized by Google



RIES'S PLAN OF WIRE DISTRIBUTION.

Digitized by Google

admit one or more men, and is also provided with suitable racks, shelves and compartments for properly carrying and supporting conductors of different kinds. The conductors carried by the conduit are divided into classes according to the kind of current carried by them, and each class is carried independently and in separate compartments. Induction between the different classes of conductors is prevented by the iron partitions and walls of their respective compartments, which being connected with the earth at intervals by means of the tubular supporting posts and the underground distributing conduits connecting therewith, act as an induction screen or shield by receiving into their greater substance the induced currents generated by the respective conductors, and thereby prevent these currents from escaping to or affecting the conductors in any of the neighboring compartments.

At intervals of every ten blocks the main conduit is provided with a "distributing" or "district" station, at each of which an elevated branch conduit extends in opposite directions from both sides of the main structure, and traverses its respective portion of the city in a direction at right angles to that taken by the main conduit. These branch conduits are in the form of a rectangular tube, whose interior is, like the conduits of the main structure, provided with a longitudinal central passage to permit of thorough personal inspection, and a series of shelves and compartments on both sides of the central passage for holding the conductors. This tubular conduit, however, need only be constructed on one side of the street, and is supported by means of a single line of tubular posts, which are erected at proper intervals along the curb. At every alternate street along the line of the branch conduits one of these supporting posts is connected with short underground distributing conduits extending along such alternate streets for a distance of not more than five blocks on both sides of the branch conduit, through which the necessary wires or conductors are led from the elevated branches to the stations or houses located on the row of blocks between which the distributing conduits extend. The distributing conduits are provided with junction-boxes from which an underground service tube runs to an area or courtyard in the centre of the blocks facing the distributing conduits, and there terminates in a tubular upright service post from which the various conductors radiate and enter the rear end of the surrounding buildings.

This arrangement will be readily understood by referring to the accompanying plan, which illustrates a portion of a city to which this method of distribution is applied. The conduit system is shown by the black lines, the double lines representing the elevated portions, that is, the main and the several branch conduits or ways, and the smaller lines representing the underground portions, or in other words, the distributing conduits and service tubes. The main conduit, at its junction with the several branches, is provided with elevated distributing stations; 3, 4, 5, etc., which, as will be seen, are placed ten blocks apart. The city, on either side of the main conduit, is divided into as many supply districts as there are branch conduits, as indicated by the dotted lines, and each branch conduit extends directly through the centre of its respective district. These supply districts measure ten blocks in breadth, and in length extend from the central main conduit to the city limits; if however, this latter distance exceeds twenty blocks, an auxiliary conduit, either elevated or underground, should connect the several branch conduits with each other. Each district is sub-divided into a number of sub-districts, each consisting of a group of ten blocks arranged in two rows of five blocks each, between which rows extends an underground distributing tube connecting with one of the posts that support the elevated branch conduit. The connection with the several blocks is made by means of service tubes that extend from suitable junction boxes in the distributing conduits, either to an upright tubular distributing or service post in the centre or court yard of each block, as shown in the first two sub-districts of the branch 3 R and 5 R, or to a "block circuit" or "curbstone" conduit, as shown at 4 R.

It will thus be seen that by means of this system it is possible to thoroughly supply ten blocks with electrical conductors (and other classes of service as well) by means of an underground distributing conduit a little over four blocks in length, and with the use of only three junction boxes. It will also be noticed that *no individual block is in direct* connection with either the main or the branch conduits, all connections with the main conduit being through the service tube of the block, to the distributing conduit of the sub-district of which the block forms a part, to the elevated branch conduit in whose district the sub-district is located, and then to the elevated main conduit in the order named. Consequently, the supply and connections to an entire district can be governed and held under control from the distributing station of such district, and the supply to any particular sub-district can likewise be changed or controlled by means of suitable connections or cut-outs at the junction of the distributing with the branch conduit, and this can be followed down so that in case of fire or other emergency, the supply of any class of current can be cut off, or the continuity of any or all the conductors or circuits on the block preserved so as not to interfere with the supply to the other blocks of the sub-district, by means of a junction box having the necessary cut-outs and switches located on each block. The distributing conduits are not only intended to distribute the conductors carried by the main and branch conduits, but also to receive conductors from telegraph offices and other stations that may be located in their sub-district and carry them, by means of the branch conduit, to the distributing station and main conduit, from which point they run to their several destinations.

Another advantage of this method of carrying and distributing conductors is that substantially all the work of repairing, making connections and additions etc., will be confined to the elevated main and branch conduits, for the reason that they carry the burden of all the wires, cables and other conductors, and thus the streets will be relieved from the constant disturbance to which they would otherwise be subjected from this source. The underground distributing conduits, being comparatively short and holding each but a small proportion of the conductors carried by the elevated branches, would seldom be called upon for repairs, but if this should become necessary, the comparatively short length and small dimension of any individual conduit, and the facilities provided for introducing additional conductors, will render this work extremely simple. It will also be noticed, that while the *aggregate* length of electrical conductors actually under the surface of the streets is considerable, *the actual underground length of each individual wire or conductor is extremely small.*

It is owing to this fact that this system obviates one of the greatest difficulties met with in operating underground electrical conductors, and that is, retardation due to the inductive influence of the earth. It is well-known that this, more than anything else, has prevented the general burying of telegraph and telephone wires and cables, and is at the present time the greatest drawback outside of the difficulty of securing the necessary subterranean facilities, to the successful construction and operation of a *complete* underground system. In the system shown the telegraph and telephone wires are carried through the elevated main and branch conduits to a point at or very near their destination and the distribution then completed by means of the short underground conduits. It is true that the grounding of the conduit compartments for the purpose of getting rid of induction and leakage will cause them to act slightly as a retarding medium upon their enclosed conductors, but this effect, it is believed, will not be nearly as pronounced as if these conductors were buried directly in the earth or in close proximity thereto, as they would be in an underground conduit system.

Having now given a general outline of this system, and

Digitized by Google

shown in what manner the requirements necessary to an electrical conduit system can be attained, and the technical and practical difficulties successfully overcome, we will now turn our attention to a brief consideration of other forms of service to which this conduit system is adapted, and which, although not directly affecting the electrical questions involved, would nevertheless have an important bearing in the consideration of the practical and financial side of the question, inasmuch as such additional forms of service will have much to do with the successful and economical distribution of the electrical conductors.

It has already been stated that the main conduit structure is divided into five longitudinal parts, of which the conduit enclosures occupy the two portions immediately adjoining the central division. The central division is bridged or floored over so that this flooring is level and continuous with the top of the two conduits, and is designed to be used as an elevated footway or promenade for pedestrians who may wish to avoid the crowds and traffic on the streets below. The two outside divisions of the main structure are intended for rapid transit purposes by means of electric railways, one side for up, the other for down trains, and the distributing stations will serve also as passenger stations. The central space below the footway and between the two conduits can be utilized for various other forms of service such as for tubes and pipes intended to carry and distribute compressed and rarefied air, tubes for pneumatic despatch and transmission purposes, tubes for collecting and delivering mail matter, and for an electric railway or telpherage system for transmitting packages of mail matter, newspapers, and general merchandise. These various forms of service, can be operated to and between the several districts of the city by means of the main and branch conduits, and if necessary, the compressed air and transmission tubes can be distributed by means of underground distributing conduits having separate compartments or divisions for the electrical and pneumatic conductors.

If the conduit system is intended to be employed for rapid transit or transportation purposes in addition to its function as a conduit for electrical conductors, the elevated branch conduits are built sufficiently strong to support an electric passenger railway upon the top of the rectangular conduit, suitable provision being made to prevent undue vibrations from affecting the conductors carried in the interior. The conduits are furthermore provided with stations at proper intervals, as shown at s 1 and s 2. The trains of the branch conduits run back and forth between the distributing and the terminal stations, while the trains of the main conduit structure run along the main structure from one end of the city to the other. The operation of this system of railways is such that the cars of the branch lines carry passengers from points on their respective lines to the station at their respective junction with the main line, from which station the transportation is completed by the trains of the main railway, or the passengers transferred from such station by said trains to another station the trains from which lead to the desired destination, thus enabling a passenger to be carried at will either between any two stations on any particular line, or (without extra charge) by a transfer at the main line, from any station on one line to any station on any other line. Thus by means of *a single system* of railways, operated in the manner described, a passenger may be rapidly conveyed from any desired portion of the city, no matter where located, to any other point in the city that he may desire to reach, and at the end of his trip find himself *within less than five blocks* of his destination.

From what has been said it will be seen that this system of distribution is not only adapted to thoroughly and practically distribute electrical conductors of every kind with the smallest amount of waste and in such a manner as to accommodate itself to nearly every form of distribution, but the conduit system is equally well adapted for any class of service that can be desired for city or district supply purposes. For instance, the distributing stations 3, 4, 5, etc., which are designed as general central stations for their several districts, from which the connections and the entire operation and traffic of their respective branch and distributing conduits is regulated and controlled (and which, when the conduit system is intended to be used for the various purposes to which it is applicable are three stories in height, and provided with passenger waiting rooms, station and express offices, rooms for receiving, numbering and distributing conductors, and for connecting, switching and cutting out purposes, and with junction and terminal facilities of various kinds) can also be very conveniently employed as district telegraph stations and telephone exchanges for their respective districts, inasmuch as ample facilities already exist from the manner of distribution employed in each district, and therefore, although the system of overhead and underground conduits is not exactly what has been aimed at by recent legislation, it is believed to be better adapted to the purpose from practical and economical considerations, and that it obviates difficulties that would be almost insurmountable in an underground system.

Baltimore, Md., Aug. 26, 1885.

THE CONSTRUCTION OF LINES FOR ELECTRIC CIRCUITS.

BY THOMAS D. LOCKWOOD.

(Continued from page 381.)

RIVER CROSSINGS.

WHEN a river is to be crossed by a telegraph, or telephone line, the first thing to be decided is whether overhead spans, subaqueous cable, or bridge, is to be employed. This will have to be determined by the surroundings. If a bridge is convenient, whether provided with a draw or not, it is well to avail ourself of its facilities. If it is a permanent structure all the way across, we may run naked wires over, on fixtures at the sides of the bridge either above or below the roadway, employing the ordinary glass insulator; or we may run a compound conductor cable containing as many wires as may be found necessary. If the bridge has a draw in the middle, it is still the preferable route; first, because the solid part of the bridge shortens the cable length, which especially in telephone lines is an important consideration; and second because in a bridge channel the cables are usually safe from the dragging of anchors.

Rivers are sometimes crossed by wires on high masts. Such a mode is not to be commended, if the river is more than a hundred yards wide, if it is a navigable stream, or if more than one wire is to be carried over. When it is done the wire should be of steel, and should be unusually well braced on each side, and the proper dip should be carefully attended to. If the banks on both sides are high, the masts need not be higher than ordinary poles.

The majority of text-books or manuals of telegraphy content themselves with describing the methods of laying, testing and operating sea cables. I propose on the contrary to give a few hints on the laying of river or short cables, as being the only ones that inexperienced persons are likely to be called upon to lay. The route must first be chosen. Of course a safe depth is not often to be found in rivers. In navigable rivers the cable always runs its chances of being dragged, but anchorage grounds are to be avoided, as also are points where the current flows with unusual strength; the best bottom for a cable in a river is mud, or silt; the only objection to sand being that it is movable, and hence apt to accumulate over the cable and to bury it, so that it cannot be raised when repairs become necessary.

If there be no choice in the bottom, the cable must be made with a view to counteract any destructive agencies found to exist at that point; for example, if the current be

Digitized by Google

swift, a large and heavy cable is required; if a rock or stony bottom be found, the cable need not be specially heavy, but must be stoutly armored. Of course the essential elements of an electrical cable for subaqueous work are the conductor and the insulator; and inasmuch as together they are very deficient in tensile strength and as they are frequently exposed to heavy strains, besides requiring protection from the numerous destroying agencies which attack them, they are almost always provided with a strong and tenacious covering in the form of armor, laid round them in plaited strands of heavy iron wire. The conductor is invariably of copper, and the highest degree of purity should be insisted upon. The gauge of the wire if single wires are used, ought, for telegraphy, to be at least No. 14, while in the multiple conductor telephone cables No. 18 should be the minimum size.

The best cables have the conductor formed of stranded wire—either three wires twisted together, or six wires twisted round a seventh; the advantages of stranded wire being greater flexibility and increased security. When stranded conductors are ordered the manufacturer should be instructed that the several wires must break joints with one another, and that silver solder must be used at the joints with rosin as the only flux.

For cables of a mile or less, the single wire will answer very well. In the insulation of under water cables there are not many materials to choose from; for long cables I should prefer to stick to the well tried gutta-percha or india-rubber; while for ordinary river cables either of the above, kerite well served with tarred hemp, and armored, or lead pipe paraffined cable, served over the lead with hemp or soft rope and armored, answer well. If any lead pipe cable is to be used under water great care must be taken in testing it before laying for pin holes in the lead. As many as fifty conductors may be embodied in a telephone cable if they are well insulated. A sufficient degree of slack must always be allowed for, and more in proportion is required with short cables than with long.

In ordering the cable it is well to specify a larger number of conductors than there are land lines to connect with, both to allow for the expansion of the system and also to allow a few spares in case any conductor should be damaged. There is considerable difference of opinion about the amount of slack which should be allowed when laying. I think, however, that in most cases slackness is to be preferred for several reasons: In the case of rivers, which scour the bottoms, or in shallow water where the cable is liable to injury, the slack is obviously useful; where, however, the banks and bed are stable and the risk from anchors is small the cable may be tightened up pretty well, taking, however, the precaution of burying several feet of cable at each end in a coil between the cable box and the river. This is useful where the cable has to be afterwards spliced, and also helps out, if the cable is attacked by lightning, as the fault due to a lightning discharge would most likely occur inside of twenty-five feet from the end of the cable at which the electricity entered. Of course when a regular telegraphic organization lays a sea cable, or a cable across an estuary or arm of the sea, it usually is provided with a vessel adapted for the purpose, together with experienced workmen, and all the necessary tools and appliances for the purpose.

When a smaller concern has a cable to lay, the location is generally a stream crossing, and the requisite facilities are not ordinarily so well supplied. Furthermore, the expense of procuring a suitable vessel is too great compared with the importance of a single cable. In these circumstances if the water is navigable, and both wide and deep, the best thing to do is to procure a steam tug on which the reel is placed, and to pay the cable out therefrom. A steam vessel is much better than a sailer, because being independent of the wind she can go in an approximately straight line from point to point. In a wide stream the terminal points on both sides can be designated by a pole or flag to guide the course. This is particularly necessary if smaller boats are used. If the water is not navigable, or if the tug cannot be procured, or if the stream is very narrow, a large rowboat may be employed, but this involves greatly increased labor. Although as a rule the reel is placed on the deck of the vessel, the free end being fastened firmly on the shore, it is quite conceivable that circumstances may arise in which this procedure cannot be adopted and in such circumstances alternative methods must be employed.

The reel may be firmly fixed on the river shore, and a rowboat well manned may be used to carry the free end over; the reel must in that event be managed by a part of the force, so as to reduce the strain on the boat. I have even known of occasions where there were no facilities at all to cross a comparatively shallow river, and where the cable was absolutely carried over the stream by a few men and then sunk.

Another way is to suspend a strong steel wire from bank to bank and use it as a suspending wire on which to carry the cable over on pulleys, sliding sleeves, or sheaves; after getting over it is very easy to drop it into the water. These expedients are only applicable of course to narrow rivers or watercourses. When narrow but deep water has to be cabled, the cable while being laid sometimes develops a wonderful tension, and if this increases to such a degree that it cannot be directly controlled, a single turn of it may be passed round a drum, and friction can then be applied to the drum by which the speed may be controlled. This is but a crude expedient but serves well enough for a short cable. Another way is to pass the cable between two blocks of wood, pressed together by leverage. It is never safe to start on a laying expedition without some means of controlling the speed and tension of the cable. In all cases the greatest care is essential to prevent kinks.

In tide water, or in rivers where there is much difference between high and low water, both cable ends should be well buried out to the mark of low water and covered with heavy planking weighted or otherwise fastened down, as nothing is worse for a cable than to be exposed to the atmosphere and sun. The connection between the cable conductor and the land line ought uniformly to be made in a cable box which should always be made water tight, and which should be attached to a pole some distance back on the shore or bank so as to be out of the reach of ordinary high water. Cable boxes at bridge draws can be attached to the first wire support at both sides of the draw. The cable must be brought to the pole in a well covered trench and led up to the box, entering it at the bottom and between the trench and cable box, must be firmly spiked or stapled to the pole, so that if the waters should rise and float the pole it will act as a buoy for the cable. From the foot of the terminal pole to the cable box a troughing is secured to the pole to protect the ascending cable, and the cable enters by a hole at the bottom of the box. The land lines come to the pole and are dropped from their insulators at the top to other insulators just above the box at which they are terminated. A well insulated wire is attached to each, and is led into the box through padded holes, the connection between it and the cable conductor being made within the box.

No cable should be left without a lightning arrester at each end, which is also placed in the box; as a ground wire for this arrester there is nothing better than the cable armor itself. The cable end may be stripped of the armor about a foot before it enters the box, and the insulator conductors brought in together and separated inside.

Solder the splice and then cover it with rubber or kerite tape. The two wires are sometimes joined by a screw connector, but this is not advisable as the screws will work loose, and the metal will oxidize.

It is far better to make a permanent splice connection, covering it as described and to run a branch wire to the arrester.

EXPERIMENTS WITH THE THERMAL TELEPHONE [1]

BY CHAS. R. CROSS.

In the *Telegraphic Journal* for 1880, page 204, Mr. Wm. H. Preece describes some very interesting experiments with a new form of telephonic receiver, consisting of a fine stretched wire, one end of which is attached to the middle of a diaphragm and the other to an adjustable support. The wire is placed in circuit with a voltaic battery and a microphone. When the microphone is actuated by the voice, the electrical undulations thereby produced in the battery circuit cause corresponding variations in the temperature, and hence in the tension of the wire, and thus the diaphragm is set into vibration so that speech is reproduced.

Mr. Preece used six "bichromate of potash" cells. He does not state the amount of the heating effect on the wire, but from what is said it is evident that the temperature of the wire was but slightly elevated.

The statement of results in the paper referred to is quite brief, and the experiments detailed below were undertaken in order to ascertain to what extent speech can be reproduced by such a receiver, both as to loudness and intensity; to study somewhat further the changes due to variation in the length and diameter of wire of different materials, under varying conditions of current strength; and, especially, to observe the effect of varying the temperature of the wire. Most of the experimental work has been carried on under my direction by Messrs. W. J. Hopkins and J. O. Ellinger, students in the laboratory of the Massachusetts Institute of Technology.

We first sought to find under what conditions we could realize the maximum loudness of speech, using platinum wire which had given the best results with Mr. Preece. For a transmitter we used a Hunning microphone, a form of transmitter in which granulated carbon is employed, the powder being loosely confined between two metallic plates. The battery used consisted of from one to twelve Grenet cells, the maximum current used being sufficient to raise the temperature of a platinum wire, .01 in diameter and about 10 inches long, to redness. In order to avoid excessive heating of the transmitter, it was placed in derived circuit with the battery and receiver. In some experiments, the diaphragm was made of firm cardboard, and in others of sheet iron.

One would naturally suppose that the larger the wire the greater would be the variations in tension and hence the greater the loudness of the resulting sound. If, however, the length of the wire is increased beyond a certain limit, the quality of the articulation appears to become very inferior, even though the loudness may be somewhat increased; and the wire tends to assume a free vibration of its own, producing a confusing after-tone.

The heaviest wire that we used was 0.0095 inches in diameter, as want of the requisite current at the time of the experiments prevented our increasing the diameter beyond this. With it a length of about 6 inches gave in general the maximum loudness, as Mr. Preece had previously observed.

Using a platinum wire .004 in. in diameter and from 6 to 7 in. long, with sufficient current to raise its temperature to dull redness, very remarkable results were obtained. Not only could the most unfamiliar conversation be understood, but words spoken into the transmitter were heard and understood with the ear at a distance of from 2 to 10 inches from the diaphragm of the receiver, the character and loudness of the sound being very similar to that obtained when a Hunning transmitter is used with an ordinary magneto receiver. Using a somewhat shorter wire at the same temperature, gave a decidedly better quality of sound, but the loudness was very materially diminished. Lowering the temperature caused a rapid diminution in the loudness of the sound.

1. Read at a meeting of the American Academy of Arts and Sciences, Oct. 14, 1885.

Almost as good results were obtained with german silver wire, a material not mentioned by Mr. Preece; but with this the influence of temperature was far less marked than in the case of platinum. In fact, quite as good results both as to loudness and distinctness of articulation, were obtained when the wire was simply warm to the touch as when it was hotter. In this respect german silver differs from any of the other materials that we used. With iron and copper but few experiments were tried, and the results were quite unsatisfactory.

It is difficult to give any numerical estimate of loudness and distinctness in such experiments as these. The following tables, however, besides furnishing a more precise idea of our results, will show the result reached in some attempts to form a numerical estimate of the relative intensity under different circumstances. The loudness of an ordinary magneto receiver when used with a magneto transmitter, spoken into with a moderately loud tone of voice, is called 10.

GERMAN SILVER WIRE, DIAMETER .007 IN., JUST BELOW REDNESS.

Length.	Nature of Articulation.	Comparative Loudness.
10½ in.	Faint, but distinct	8
7½ "	Clearer	7
5 "	Same as in last experiment	8
3 "	Poor and indistinct	4

PLATINUM WIRE, DIAMETER .0095 IN., AT RED HEAT.

10½ in.	No sound	0
7½ "	Very faint	1
5 "	Quite distinct speech	4
3½ "	No sound	0

PLATINUM WIRE, DIAMETER .006 IN., JUST BELOW REDNESS.

10½ in.	Distinct	Fairly loud.
7½ in.	No change in distinctness	Loud as magneto.
6½ "	" " " "	Louder.
4½ "	" " " "	Much fainter.
2½ "	Very indistinct	Barely audible.

NOTE.—In the last experiment the wire was cool when the shorter length was used.

PLATINUM WIRE, DIAMETER .005 IN., JUST BELOW REDNESS.

7 in.	Speech easily understood	Moderately loud.
5 "	Clearer	" "
3 "	Fairly distinct	Fainter.

PLATINUM WIRE, DIAMETER .004 IN., JUST BELOW REDNESS.

10¾ in.	Speech fairly distinct	Faint.
7½ "	Very distinct	Much louder.
3½ "	Clear	Less loud.
2½ "	"	" "
1¼ "	No sound	Inaudible.

PLATINUM WIRE, DIAMETER .002 IN., JUST BELOW REDNESS.

5 in.	Fairly distinct	5
3 "	Less distinct	9
1¼ "	No sound	0

From these and other experiments, it appears that our best results were obtained with the wire of .006 and .004 in. in diameter, there being but little difference between them. The largest wire used (.0095 in. diameter) gave very poor results, and with the battery power used by us the finest wire employed (.002 in. diameter) was equally inefficient. Mr. Preece's best results were secured with platinum wire, .001 in. in diameter. Also with the finer wire the most effective length was less than with the larger sizes. The most interesting point, however, developed in the course of our experiments is the effect of increasing the temperature, notably with platinum wire, in increasing the loudness of articulation of the thermal receiver. This will naturally be attributed to the greater expansibility of the wire at high temperatures. It is possible that with german silver the effect, good at moderate temperatures, is not bettered on heating the wire, because of a marked influence of temperature in diminishing its elasticity.

The question also suggested itself as to what effect, if any, would be produced if the microphone were placed in the primary circuit of an induction coil, and the wire receiver in the secondary circuit, so that the receiver would

Digitized by Google

only be acted upon by the induced currents from the coil. Since the heating effect varies as the square of the current, with such an arrangement difference of sign in the current could not be perceived at the receiver, and therefore one would not expect to be able to distinguish articulate speech. We thought that if any sound was produced it would be interesting to study its quality as compared with the quality of the sound actuating the transmitter. Our results, however, were negative. A sound was produced on breaking the circuit, but no audible effect was observed on speaking or shouting into the transmitter. In these experiments german silver wire was used in the hope that even at ordinary temperatures it might prove sensitive. Independent heating by a current of hot air was tried, but without success.

An attempt was also made to use the thermal telephone as a transmitter. Sir Wm. Thomson has shown in his researches on the electro dynamic qualities of metals (Math. and Physical Papers, vol. ii., p. 208), that the electrical resistance of wires is varied by their tension, and indeed it was in following out this idea that Prof. Hughes was led to his invention of the microphone (*Telegraphic Journal*, May 15, 1878).

Slight as the variation in resistance must necessarily be with such a transmitter, we yet hoped that the exceeding sensitiveness of the magneto receiver would suffice to detect it. Our results, while not at all striking, were sufficiently encouraging to lead us to hope for greater ultimate success. The thermal telephone, with a platinum wire 4½ in. long and 0.004 in. in diameter and an iron diaphragm, was placed in circuit with a battery of 10 Grenet cells and an ordinary hand telephone receiver. The current was sufficient to heat the wire almost to redness. All the joints of the wire were soldered to prevent the possibility of microphonic action, which at first caused some annoyance, but which was readily recognizable by the scratching sound produced by it. With the joints thus soldered, and every precaution taken to avoid such microphonic disturbances, we succeeded in hearing and understanding at the receiver the word "hallo," and some brief familiar sentences. The sound was low but distinct and clear, and in quality quite unlike the sound produced by microphonic action. There seems to be no doubt that electrical undulations were produced in the circuit by variations in the stress to which the heated wire was subjected. Similar results were obtained with a smaller number of cells, even down to one, but the sound was then exceedingly faint and scarcely audible. Speech was also transmitted by a thermal transmitter in which german silver wire was substituted for the platinum. It may be that the more marked results on heating the wire to a higher temperature by the use of a stronger battery indicate that at such a temperature the electrical effect of changes in stress in varying the resistance of a wire is increased.

Mass. Inst. of Technology, June, 1885.

[NOTE.—During the discussion that followed the reading of the foregoing paper, Prof. A. E. Dolbear stated that he had experimented with the thermal telephone receiver as early as 1878, using a few gravity cells, and transmitting speech audibly, though very feebly.—C. R. C.]

MEASUREMENT OF THE STRENGTH OF TELEPHONE CURRENTS.[1]

BY CHAS. R. CROSS AND JAMES PAGE.

So far as is known to the authors of the present paper no measurements have ever been made of the strength of such telephone currents as are actually used in the transmission of speech. The few figures that have been given are estimates rather than measurements. Some very interesting results are given by Dr. C. J. Blake (*Jour. Soc. Tel. Engineers*, 1878), regarding the logographic values of the different vowels as determined by the throw of the needle of a mirror galvanometer used in connection with a magneto transmitter. This logographic effect, however, should be carefully distinguished from that of the alternating currents utilized in the continuous transmission of sound, as, even with apparatus suitable for the measurement of such currents, it is liable to mask the phenomena to be studied unless care be taken to avoid such disturbing effects.

The lack of figures in so interesting and important a subject as the one under consideration, arises from the fact that an electro-dynamometer of some form must be used for the necessary measurements, and an exceedingly sensitive instrument is essential in order to obtain sufficient deflection to give results of any value.

A form of electrical balance similar to that figured by Maxwell (*Electricity and Magnetism*, 2d ed., vol. ii., p. 342) was at first constructed, but this failed to give satisfactory results. Subsequently, success was obtained by using a Kohlrausch unifilar electro-dynamometer, made by Hartmann, of the form described in Wiedemann's *Annalen*, vol. xv., 1882, p. 550. The instrument was modified by removing the heavy movable coil, furnished by the maker, which was of altogether too low resistance for our purpose, and replacing it by a lighter and closely wound coil of No. 36 (B. and S.) copper wire with a suspending wire of the same gauge and 40 centimetres in length. The resistance of the instrument was 206 ohms, that of the suspended coil being 166 ohms. In some of the experiments the metallic vane which, in the instrument as described by Kohlrausch dips into a vessel of dilute sulphuric acid, was removed, and a needle point dipping into mercury substituted, the connection with the telephone being made through this. But the greater freedom from disturbances when the vane was used made it preferable. The rapid alternation of current prevented any difficulty from polarization, as was shown by the fact that with a source of sound of constant intensity the same results were obtained whether dilute sulphuric acid or mercury was employed. A reading telescope and scale graduated to millimetres served to determine the deflections of the dynamometer coil, the telescope being at a distance of 1.5 metres from the mirror.

The dynamometer was usually placed in the secondary circuit of a small induction coil, the resistance of which was about 800 ohms. The microphone transmitters were placed in the primary circuit, with two Grenet cells arranged in parallel circuit. When the magneto transmitter was used it was placed directly in circuit with the electro-dynamometer.

The dynamometer was so placed that when no current was flowing the axis of its suspended coil was at right angles to the magnetic meridian. No special pains were taken to secure this accurately, as the action of the deviating couple due to the earth's magnetism was found to be quite negligible in comparison with variations caused by unavoidable differences in the intensity of the sounds acting upon the transmitter. Deflections of the suspended coil were read by the use of a mirror, telescope and scale, as the ordinary method of bringing the scale-reading back to zero by moving the torsion head of the instrument could not be used, since it was impossible with the voice to sustain a note for a sufficient length of time. The deflections were therefore read by the observer, and the strength of the current subsequently determined from these by the following method: A Daniell cell was placed in circuit with the dynamometer, using a mercury contact to avoid the polarization which would ensue with dilute sulphuric acid, and by means of a rheostat interposed in the circuit the resistance was varied until deflections were obtained corresponding with those given by the telephone currents. The electromotive force of the cell divided by the total resistance in the circuit gave the current corresponding to any given deflection. A galvanometer was also inserted in the circuit, but as there was some uncertainty about its

1. Read at a meeting of the American Academy of Arts and Sciences, Oct. 14th, 1885.

Digitized by Google

constant and law of deflection which we were prevented from determining by want of time, the method already stated was relied upon, merely using the figures given by the galvanometer as a check upon the results. The current strength as given in this paper is therefore the strength of the steady current, which gives the same dynamometer reading as the alternating currents of the telephone. No correction for the self-induction of the dynamometer was attempted, as the range of variation in the readings shows that at the present stage of our research no real increase in accuracy would be secured by doing this.

The absence of any means of obtaining a definite and constant intensity of the voice renders it very difficult to obtain uniformity in results. Care was, however, taken not to continue the experiment very long at any one time, as the voice of the singer or speaker became wearied and was less under control.

In telephonic experiments care must be taken, as already intimated, to avoid the logographic disturbance that arises from the strong air pressure developed on beginning the utterance of different sounds, as the magnitude of the temporary deviation produced by this often far exceeds the permanent deflection which is given by the continuous telephone current. This can be done by raising the voice very gradually, but a better method, which we have employed, is to interpose a key which keeps the circuit open until the sound is fully developed. Then on closing the circuit, the deflection quickly becomes steady, and the disturbance in question is avoided.

Measurements were made with the Hunning, Fitch, Blake, Edison and Bell magneto transmitters. The Hunning transmitter uses carbon in a granulated form, and the Fitch employs two hard carbon discs as electrodes. The structure of the other transmitters is too well known to require any description.

The vowels *a*, *o*, *u*, *i* (German sounds), were spoken or sung into the transmitter successively, all at the same pitch, viz.: the B of 480 vibrations, and with the same intensity as nearly as this could be realized. The deflections obtained are given below in full, in order to furnish some idea of the degree of uniformity obtained. Several separate series are given for each transmitter. In some cases the loudness of the voice varied somewhat in passing from one series to the next.

The readings are given in centimetres and tenths.

Some experiments were also made upon a Dolbear electrostatic receiver in circuit with a Hunning transmitter and high resistance induction coil. The currents produced when speech was readily transmitted and reproduced by the Dolbear receiver were too slight to be measured by the dynamometer, although amply sufficient to reproduce speech in a magneto receiver interposed in the circuit.

At first sight some of the results given in the preceding tables are quite unexpected. Thus in some cases the magneto transmitter gives as great or even a greater current than the Blake carbon transmitter, although as used in actual practice the latter is far louder. This probably comes from the fact that with the magneto transmitter the lips were habitually placed close to the mouthpiece of the instrument, so that even if the same actual strength of voice was used the effect on the diaphragm of the magneto was greater than on the diaphragm of the Blake transmitter. It was impossible to use the same loudness of voice with the lips close to the mouthpiece of the latter transmitter, as the scratching sound which always appears with a microphone too strongly excited became very marked. We therefore, while keeping the voice at the same intensity, removed the mouth farther from the transmitter until the scratching ceased. In fact, the difference in the size and shape of the mouthpieces of the different instruments and the position of the mouth in speaking, whether pressed against the mouthpiece or at a little distance from it, always affect both the absolute and relative strength of the vibrations of the diaphragm with different vowels, and hence, of the resulting currents. A further interesting illustration of this will be seen by comparing the results with the Hunning and Edison transmitters.

In another series of experiments the sound of a C_4 stopped organ pipe giving 512 vibrations per second was substituted for the voice. Very great constancy in its intensity was secured by blowing it with a blast and using a very large bottle as a pressure regulator. Three tubes were inserted through the cork of the bottle. Through one of these the air from the blast entered the bottle; through a second it passed to the organ pipe; while the third tube was drawn to a small aperture at its extremity which allowed a greater or less quantity of air to pass out, according as the pressure from the blast tended to increase or diminish. Observations were made at intervals for ten

Digitized by Google

minutes. Only slight oscillations of the coil occurred during this time. The following are the mean readings with different transmitters:

Hunning........7.9 Blake..............0.7 Magneto.........0.5
Fitch............3.4 Edison...........0.2

The strength of the current in ampères in the different experiments was as follows:

In the case of some of the very small deflections observed, the current was calculated on the assumption that the deflection varied as the square of the strength of the current.

A few preliminary experiments were made, using a method by which we hope to obtain further results. A Thomson quadrant electrometer was used with the telephone on the same plan as that originally suggested by Joubert for its use with dynamo machines, giving alternating currents. The needle and one pair of the quadrants were connected with one terminal of the telephone, and the other pair of quadrants with the remaining terminal. There was not sufficient time at our disposal to obtain any series of measurement by this method, but results were reached which give encouragement as to its availability. It is possible that this method may prove especially useful in the study of electro-static telephones.

The results given in the preceding pages are to be regarded only as preliminary to a more extended series of measurements. But while they are yet necessarily somewhat meagre, they seem at least to show: first, that an electro-dynamometer of a simple construction is sufficient not merely to detect but also to measure telephone currents; and second, that the strength of these currents, especially when good carbon microphone transmitters are used, is far in excess of what has hitherto been supposed.

Mass. Inst. of Technology, Boston, June, 1885.

THE ACTUAL CANDLE POWER OF ARC LAMPS.[1]

BY J. S. ADAMS.

THE laws of light, involving as they do the principles of the higher mathematics, are not generally understood, especially those pertaining to the lighting of large areas by electricity. But in view of certain strictures upon the present system of street lighting in Elgin, made by a prominent alderman, we give the following words of explanation, which, without technicalities, will be generally understood. The only object in writing this article is to place the electric system in its true light before the people of Elgin.

In every city where the electric light has been introduced hundreds of persons seeking for facts, and unable to convince themselves that the light from the so-called 2,000 c. p. electric lamp is equal in quantity to that from 2,000 standard sperm candles, burning at the rate of 120 grains each per hour, have asked from persons whom they supposed to be able to impart the desired information: "What is the actual candle power of the light from an electric arc lamp of 2,000 nominal c. p.?"

In consequence of the lack of reliable data upon this subject, the parties questioned have not generally been able to give any positive answer to this question; but it has been admitted by well informed advocates of the electric light that the actual average light from these lamps is from 500 to 1,000 c. p.

"Why, then, are they named 2,000 c. p. if they do not give an actual average of 2,000 c. p. of light?"

In answer to this question it may be said that electric arc lamps, in common with many other articles, animals and persons, have received their titles in consequence of their best possible, instead of their average, performances.

One of these lamps tested by a photometer, under the most favorable conditions, will at times show from 2,000 to 2,200 c. p., and from this fact it has received its name or title—a 2,000 c. p. lamp—and by this name it is known throughout the civilized world.

"But this does not answer the original question: What is its actual average candle power?"

In answering this question, and in understanding the answer, it is necessary for us first to understand that the light from an electric arc lamp is not radiated in nearly equal quantities at all angles above and below the horizontal plane, like light from the ordinary lamp or candle, but that in consequence of the formation of the electric arc in the concavo-convex space between the ends of the upper and lower carbons, a large proportion of the light is projected in the form of a cone below the horizontal plane of the lamp, the most powerful rays being at an angle of 45 deg. The candle power of the light from the same lamp, and at the same moment of time, is therefore materially different when measured at different angles below the horizontal plane of the lamp.

This fact is clearly demonstrated in the following table, which gives the results of a series of photometrical measurements made at the Philadelphia electrical exhibition, and shows the intensity of the light from a Van De Poele electric lamp of 2,000 nominal c. p., at different elevations, noted at intervals of five degrees, from 0 to 60 deg.:

Elevations.	Candle power.
0 deg	450
5 deg	525
10 deg	620
15 deg	710
20 deg	805
25 deg	920
30 deg	1040
35 deg	1180
40 deg	1290
45 deg	1340
50 deg	1290
55 deg	1020
60 deg	675

Average candle power, 913.

"According to the above figures we find that the actual average candle power of these lamps is only 913, instead of 2,000; are not the people being defrauded to the extent of this difference?"

A statement of the quantity and relative cost of the light formerly in use as compared with the electric light

1. Elgin *Daily News*.

will enable the people to judge for themselves of this matter. Previous to the introduction of the electric light, there were in use in the city of Elgin 105 gas lamps, of 16 c. p. each, making a total of 1,680 c. p. of gas light, and 1,770 of naphtha, or a grand total of 3,450 c. p. of light. There are now in use 33 electric lamps of 913 c. p. each, a total of 30,129 candles; more than eight and one-half times as much light as was formerly furnished by the gas and naphtha lamps. The gas lamps were formerly extinguished at or near midnight. The electric lamps are kept burning until morning, that giving fully double the time of the former service, and thus doubling the quantity of light furnished, making the proportions more than 17 of electric light to one of gas and naphtha combined. For the former service of gas and naphtha lighting, the city paid an average of $455.61 per month. For the present electric light service the city is paying the sum of $666.66 per month, or 46 per cent. more than they paid for gas and naphtha. An extra cost of 46 per cent. for the lighting of a very much larger area, and the furnishing of more than 17 times as much light, does not appear to be a very bad bargain for the city. The photometrical measurements of the light from the different lamps exhibited at Philadelphia, have answered not only the question of the actual candle power of these lamps, but have also demonstrated the great economy of the use of the electric light, and the wisdom of the city government in its adoption.

CYLINDER ARMATURES.

BY CARL HERING.

If a continuous insulated wire be wrapped around a cylinder lengthwise, the cylinder being turned on its axis slightly after each turn of the wire (as indicated by its numbers 1 to 16 in fig. 1), and if the end of the wire be

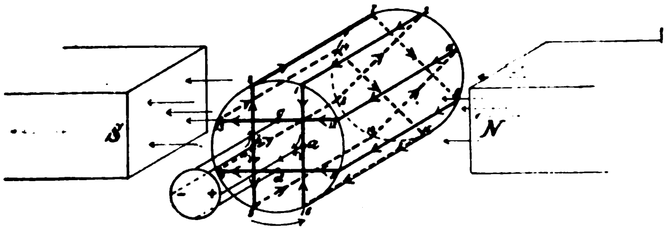

FIGURE 1.

soldered to the beginning, it will be the simplest form of a cylinder armature. If this be revolved between a north and south pole, or in a magnetic field, as it is called, currents will be induced in all the wires as they pass near the poles, and from the nature of the winding they will be found to add up to two distinct currents. From the well-known laws of Ampère and Lenz, the direction of these currents can be determined; but as it is very easy to make a mistake in applying these laws to dynamo machines, the following more simple rule used by the author may be found preferable. The direction of the lines of magnetic force is generally represented as coming out of the north pole and into the south pole.[1] Now, in looking at the commutator end or front end of the armature, *if the armature be rotated opposite to the hands of a watch, the currents on that end of the armature will go in the same direction as the lines of force.* In fig. 1 the currents, according to this rule, will flow from 12 to 13 and from 5 to 4. By following these wires we see that the currents on the side toward the north pole flow from the back to the front of the armature, and, of course, in the reverse direction on the side toward the south pole.

Placing arrows on all the wires on the curved surface of the cylinder and beginning at No. 1 for instance, we find that the currents all add up as we go around until we come to a point, *b*, where it meets a reverse current. If we start at 16 and follow the current around to 15, 14, etc., we come to the same point, *b*, showing that in two halves of the endless wire the current is induced in two opposite directions, or in other words, two halves of the armature are in multiple arc, like two batteries in which the carbons are connected together as one pole and the zincs as the other. The points *a* and *b* are therefore the two places where the currents must be taken off. These and all similar points, *c* and *d*, which come into this position during a revolution, should therefore be connected with the commutator strips against which the fixed brushes rub to lead off the current. *a* will be the positive pole and *b* the negative. Each wire of the armature will have to carry only half of the current which the machine gives, while the total electromotive force will be produced by half the number of turns on the armature.

There are a number of different methods of winding a cylinder armature, all like the above in principle but differing in details, owing to certain difficulties to be overcome. The principal one of these difficulties is due to the fact that as the two halves of the armature are in multiple arc or parallel circuit, it is very necessary that the same electromotive force should be induced in both halves, otherwise when the circuit is open the excess of electromotive force of one half over the other will cause an internal current to circulate in the armature wires and will therefore absorb work when no current is required in the external circuit. As the electromotive force depends only upon the number of lines of force cut per second, it can be kept the same in both halves by wrapping the coils so that the two halves shall have the same mean radius, that they shall have symmetrical positions with respect to the axis, and shall always be in the same or in similar parts of the magnetic field. It is also very desirable to have a "balanced" magnetic field, that is, one which is the same size, shape and magnetic density at the north as at the south pole. Owing to iron baseplates, bearings, etc., the field is frequently unbalanced, but for many systems of winding it is not essential to have it balanced, as it affects both halves alike. This is one of the advantages of the cylinder armature over the Gramme, as in the latter the unbalanced field cannot be eliminated by the winding.

As the difference of potential[2] at the ends of the two halves of the armature wires which are in multiple arc depends not only on the electromotive force of the coils, but also on the resistance of the two halves, these resistances should be equal, or what is the same thing, the lengths of the wires of all the coils should be equal. As the coils cross each other at the two ends of the armature, a so-called "head" is formed there, which grows larger for each coil, so that the last coils will always be somewhat longer than the first. In a well designed armature this difference is very slight. The armature should not be too short as compared with its diameter, and a method of winding should be selected which has as few wires crossing each other as possible, so as to make a small head on the armature.

Another important point to be remembered in winding armatures is the continual short circuiting of from one to four coils. Each brush has to be thicker than the insulation between the commutator strips in order not to break the circuit while it is passing from one to the other; at that moment it touches two commutator strips,

1. This is the direction which would be indicated by a compass needle with an arrow head on its blue or north seeking end. Lines of force have no one direction of action such as the force of gravity, they merely have a certain position in space; but it is often very convenient to consider them as having such a direction, and the above, we believe, has been generally adopted as their direction.

2. The important distinction between the terms "electromotive force" and "difference of potential at the poles," we regret to say, is not always made in English as it is in German and French. The former is the original or greatest difference of potential produced by the battery or machine, while the latter is the available potential at the poles, or the electromotive force diminished by the amount absorbed in overcoming the internal resistance, and, therefore, depends upon the current supplied or upon the external circuit. They are equal to each other when the circuit is open.

Digitized by Google

and as each strip represents the end of one coil, there will be a coil short circuited by each brush every time the brush passes over the insulation between two strips. This can be shown by placing only one brush on the commutator of a machine whose magnets are excited by another dynamo; bright sparks will often be seen, especially when the brush is moved around to different parts of the commutator. When the brushes are too thick or when they lie tangential, they sometimes cover two of these insulations, there will then be two coils short circuited by each brush, and in many cases sparks and heating of armature may be expected. As this short circuiting cannot be avoided, it is necessary to bring those coils either in the neutral line or both halves on one side of the neutral line; in either case no current would then be produced in them, even if they are short circuited. If this is not done there may be bad sparking and heating of the armature (often attributed to the iron core), accompanied by the corresponding loss in efficiency. By taking many commutator strips and correspondingly few windings in each coil, there will be less potential produced in each coil and, therefore, less sparking and heating due to short circuiting.

Sparking at brushes is also probably due to the self-induction of the coils, and as this varies as the square of the number of windings, it is another reason for making the number of windings as small as possible and the number of commutator strips as great as possible. Other reasons which we cannot consider here lead to the same conclusions.

Suppose there were 16 commutator strips, then there are 16 coils or twice 8 in multiple arc. Every sixteenth of a revolution two coils are short circuited, so that there will be alternately 8 and 7 effective coils in multiple arc, thus varying the resistance and potential 32 times for each revolution. The internal resistance will vary $\frac{1}{8}$ or 12½ per cent., which may be sufficient to produce quite a variation of current. If there are an odd number of coils this will not be the case, as there will always be one coil and only one, short circuited by either one brush or the other, but never by both at one time, which is very much in favor of using an odd number of strips.

When the number of strips is small or an even number, the current must necessarily pulsate more. Such a current may be troublesome, as it may cause errors in calculation and measurement due to self induction. It increases the apparent resistance of magnet coils, and causes errors in most voltmeters in use, while the simple and convenient Ohm's law will not always be correct unless the troublesome factor of the counter-electromotive force due to self induction be subtracted from the reverse difference of potential. Whether the errors are appreciable or not depends upon the quantitative relations.

(*To be continued.*)

LIABILITIES OF TELEGRAPH COMPANIES AS AFFECTED BY PRINTED CONDITIONS.

BY J. P. KIRLIN.

The blanks upon which telegraph companies require persons to write their messages for transmission, have immediately above the address line, the following printed request: "Send the following message, subject to the terms printed on the back hereof (or subject to the above terms), which are hereby agreed to;" and on the back of the blank, or at the top, among the conditions referred to, differently worded by different companies but always of the same import, is found this one: "It is agreed between the sender of this message, and this company, that said company shall not be liable for mistakes or delays in the transmission or delivery, or for non-delivery, of any unrepeated message, whether happening by the negligence of its servants or otherwise, beyond the amount received for sending the same." The question now to be considered is, does a person who, without dissent, writes the message he wishes communicated, on such a blank, assent to this provision, and contract away his right to claim damages of the company, should the message fail to reach its destination, or arrive in a mutilated condition.

Now a telegraph company, either because it is bound to transmit intelligence for the public generally, or because the privilege of taking private property under the right of eminent domain is invoked in its favor, may be said to be in the exercise of a public calling; and is therefore under obligation to treat the public reasonably and fairly. It is liable to suit by a private individual if it refuses to transmit a proper message. It is also liable in case of refusal to transmit it for a fair price. Reasonableness and fairness, therefore, being the tests by which its dealings with the public are judged, the simple question to which the attention of the courts is addressed is this: Is the imposed condition reasonable and fair? We shall see that different courts answer the same question in different ways.

On one side it is claimed that as the sender of a message assents to the conditions, subject to which he asks the company to send the message, he should not afterwards be allowed to assert they are unreasonable or unfair. On the other it is contended that the condition is imposed, whether the sender wills or not; that he must assent to it, or appear to; that it is unreasonable, unfair, nullifies the contract, and is void. Which view is correct?

The argument of the telegraph companies is forcible and plausible. They contend that having printed the condition on their blanks, together with a notice calling the attention of the sender to it, and a notice that he is deemed to agree to the condition, subject to which he requests the company to send his message, he is subsequently estopped, in the absence of fraud, from denying that he assented to the condition, although in point of fact he did not read it. So far the reasoning is sound. One who writes his message on such a blank has abundant opportunity to read the matter printed on it; indeed he is asked to do so. He gives the company every reason to infer that he does assent and leads it, perhaps, in that supposition, to contract with him at a lower rate than otherwise. He should not, therefore, be permitted to avoid the incorporation of this condition in his contract, on the ground that he was ignorant of its import, otherwise he would profit by his own neglect. But it is further claimed that this condition forms a part of the consideration of the contract. The offer being to serve for a certain rate if the sender agrees to assume all risks, or at a higher rate if the company assumes a greater responsibility for damages. True, this arrangement ignores the fact that the condition is imposed upon the sender, and is not of his own seeking; that the agreement in case of a repeated message is to pay only fifty times the cost of sending, and not the real damages; and that the offer to insure the communication, is an offer to make a separate contract for which there is no consideration. Still in New York, Massachusetts, Pennsylvania, Michigan, Kentucky, North Carolina, and California, the highest courts have decided that a stipulation exempting the company from liability for any mistake or delay in the transmission or delivery of a message, or for not delivering the same, beyond the sum received for sending it, unless the sender orders the message to be repeated, and pays half the regular rate additional, is a reasonable and fair precaution to be taken by the company, and binding upon all who assent to it, so as to discharge the company from liability beyond the amount stipulated, for any cause, except wilful misconduct or gross negligence.

There is, on the contrary, a much more numerous class of decisions which hold that in so far as this condition attempts to exempt the company from the results of its own or its agents' negligence, it is void and of no effect. It is allowed in these cases that a telegraph company may, by special agreement or by reasonable rules and regulations, limit its liability to damages for mistakes and delays in the transmission of messages arising from atmospheric influ-

Digitized by Google

ences and other kindred causes; but it cannot claim immunity from liability where the mistake or delay or non-delivery results from negligence. An exemption of that kind is here regarded as contrary to the policy of the law, having a tendency to discourage the exercise of that care and skill, which a due regard to the public interests requires of all who engage in a public calling.

The argument of the supporters of this view is that the sender, in contracting with the company, is not in a position to protect himself, and that the law therefore must protect him. The parties in making the agreement do not stand on an equal footing. The sending of any particular message is of little moment to the company; it may be of infinite importance to the sender. Oftentimes he cannot stop to argue, or sue the company for refusing to make its ordinary, as distinguished from its special contract. The business in hand must be attended to at once, if at all. All the companies impose the same terms. There is no choice between the different lines. He is accordingly obliged to accept the condition imposed. For the time being the employer is under a sort of moral duress and is compelled to submit to such terms as the company in its corporate greed, chooses to impose. The transaction thus becomes a cat and mouse contract, which the law refuses to sanction. The courts say that as not only single individuals, but everybody—in a word the public—is compelled to accede to these terms, the question becomes one of public importance; and the law as the protector of the public declares that the condition imposed in the manner indicated, is unfair and unreasonable; and in so far as it attempts to exonerate the company from the consequences of neglect, is absolutely void. This is the view which obtains in the courts of the United States, England, the Dominion of Canada, and in the States of Ohio, Maine, Illinois, Iowa, Colorado, Wisconsin, Georgia, Arkansas, Virginia, Missouri and South Carolina. In other states where the matter would probably be determined in the same way, no cases have yet reached the superior courts.

But even in those states which give the widest latitude to the companies in construing these conditions, no exemption is allowed unless the instance falls clearly within some stated exception. The ingenuity of the courts in finding a path for justice through and between the snares which technical skill has attempted to throw about the unwary, is both curious and instructive. For example, delay in the transmission has been held not to include delay before or after transmission. And the clause exonerating the company from liability "for mistakes or delays in the transmission or delivery, or for non-delivery of any unrepeated message beyond the amount received for sending the same" has been decided not to cover the case of a failure to place the message on the lines; an alteration before transmission; an alteration after transmission; an alteration after transcribing; or an alteration in transcribing at the place of destination. From which it appears that in the jurisdictions where most leniency is shown the telegraph companies, the most stringent rules of construction are nevertheless applied, and all rights which the sender has not most clearly bargained away are reserved to him and saved.

[It may be well to add that telegraph companies have in practice recognized the right of their customers to claim actual damages, by paying such demands in full, and deducting the amount from the salary of the employé who was supposed to be at fault even when his negligence could not be actually proven. This policy has been pursued for the pacification of "good customers," the transfer of whose business to rival companies would be a more serious loss than the payment of the claim, especially where the burden of expense could be readily placed upon the shoulders of a defenceless third party. This is the more unjust and indefensible when such errors on the part of a receiving operator are as a matter of fact unavoidable, being due to the imperfect operation of the modern "improved" apparatus, at the high rate of speed at which the work is required to be done.—EDITOR.]

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

COAL CONSUMPTION ON THE ELEVATED RAILWAYS.

[40.]—I see by a paragraph in the last ELECTRICIAN AND ELECTRICAL ENGINEER, referring to an account in the "Car Builder" for July, that some tests of the locomotives on the Third ave. elevated railroad were made by Mr. Angus Sinclair, to ascertain their actual horse-power and coal consumption. The indicator cards taken by him showed them to exert an average of 77.8 h. p., and to consume an average of 5.8 lbs. of coal an hour per h. p. I refer to it here because it is so satisfactory a verification of the results arrived at by a theoretical mechanical calculation, taking into account the stops, and agrees so closely with the results of such a calculation which I gave in the ELECTRICIAN AND ELECTRICAL ENGINEER for May, in which the power came out 75 h. p., and the average coal consumption 6.6 lbs. an hour per h. p. The results of 5.8 lbs. of coal, which is even less than I made it, is surprisingly low, and shows how little margin there is between the performance of these locomotives and that of stationary engines to make up for the losses that must necessarily occur in transmitting the power by electricity. If any one can take the elevated railroads and operate the trains by electricity generated by stationary steam engines, so as to obtain each h. p. on the track with less or materially less than 5.8 lbs. of coal per hour, I for one electrician would like to know how it can be done.

CHARLES G. CURTIS.

INTERESTING TELEPHONIC EXPERIMENT.

[41.]—In a communication recently published in the London *Electrical Review*, the writer describes a number of experiments in relation to microphonic transmission of sound. In circuit with a carbon microphone and telephone receiver he placed an automatic transmitter, in which he used a ribbon of paper having a line of small holes close together, running longitudinally through the centre, similar to that used in the Wheatstone instrument. The "automatic" was put in motion, allowing the current to pass through the microphone. The continuity of the circuit was continually broken, and words spoken directly to the carbon microphone without the intermedium of a diaphragm and without any substance whatever below the carbons were distinctly heard from the receiver, the articulation being as perfect as when the current was continuous. The writer has come to the conclusion that an undulatory current in a closed circuit is not necessary for telephonic transmission, and considers Bell's theory to the contrary thus experimentally disproved.

Having myself within the past two years, conducted a series of experiments in the same direction, I am prompted to make a few remarks upon this subject; and while I thoroughly agree with the aforementioned correspondent, my investigations have enabled me to go a step farther. Not long ago a scientific paper published an article on the theory of the carbon microphone, in which are quoted the opinions of some of our most prominent electricians and scientists.

All (with one or two exceptions) agree that variations of current passing through a carbon microphone are produced by pressure of the carbons against one another. Being a firm disbeliever in the variation of resistance theory, it is here that I differ. The statement that a certain theory is not necessarily true simply because it is backed up by a long list of scientific names, is one that cannot be ignored; and neither should "accepted" theories always be relied upon, even though seemingly substantiated with proof.

My theory of the action of a current in a battery transmitter is certainly a peculiar one. Briefly, it amounts to this: that the invisible electric current is *itself directly influenced* by the impacts of air affected by the voice, and that the microphonic contacts have *nothing whatever* to do with the transmission of speech in the sense of producing electrical undulations by variation of resistance in the circuit.

In order to substantiate this theory, one of my first experiments consisted in affecting the current in a sufficient degree to deflect the needle of an ordinary detector galvanometer by pro-

Digitized by Google

ducing sound upon a microphone (?) transmitter, the carbon "contacts," instead of being in direct electrical connection with each other, were, *fully one-eighth of an inch apart.* This may appear incredible but it is nevertheless true. Not only have I succeeded in producing a telephonic receiver without the use of either magnets, diaphragms, wire, or resonating cases of any sort, but also in transmitting articulate speech to considerable distances with a break in the conducting wire. At the conclusion of my investigations I hope to present to your readers a full account of these experiments in detail, and elucidate my theory in regard to the electrical transmission of sound. WM. A. J. KOHRN.

NEW YORK AND VICINITY.

Electric Lighting in New York City.—The Stock Exchange takes Charge of Reporting Quotations.—Enterprise of the Commercial Cable Co.—The Badly Ventilated Western Union Operating Room.—Electric Lighting and Pole Permits in New Jersey.—A New North River Cable.—Unpleasantness among the Wire Manufacturers.—The "Special Delivery" Postal Innovation.—Edison's Gift to Cornell University.

THE average traveler must now deem New York city pretty thoroughly lighted with electricity. Along the river fronts, up Broadway, through the principal avenues, along the streets leading to the ferries, and in the city parks, over the East river bridge, together with a large number of private lights, notably on the Bowery, it will be readily seen that those portions of the city which come under the eye of the casual visitor are thoroughly illuminated. Should it eventually prove true that the existing companies will abandon arc lighting rather than place their wires underground, it is pretty certain that the public will not be ready to return to the old system of street lighting. The business is now amicably divided between the Brush and United States companies at the contract price of seventy cents a night, which is probably satisfactory at the present cost of carbons. Incandescent lighting is also becoming quite common in the city, especially in new apartment and office buildings. It would doubtless be still more prevalent but for the practice of duplicating it with a gas system to be used in the case of an emergency. There appears to be no good reason for this, for although electricity may occasionally fail, more care would be exercised in giving it proper attention, if it was not understood that gas could be at once utilized in its place.

The Edison Electric Illuminating Company has just declared a quarterly dividend of one per cent., the profit being derived from the operation of its central station on Pearl street.

A radical change in reporting stock sales was made on the 1st of October. Since the beginning of this important branch of the telegraph business in 1868, this work has been done by Morse operators, employed by the different companies, which received the privileges of the floor of the Stock Exchange. When competing companies were in the field, each had its own corps of reporters, working independently of the others. There were at one time three, and since the advent of the Commercial Telegram Company, there have been two sets of reporters. This work has now been undertaken by the Stock Exchange, and is in charge of R. J. Hutchinson, who has been identified with stock reporting since the days of the Manhattan Quotation Company, in 1872. Six operators were dispensed with under the new arrangement, which places the two companies on an equal footing in getting quotations, with the result that in an active market, the Commercial tickers are far ahead of the Gold and Stock. This should have the effect of hastening the introduction of the Scott printers, which it is expected will turn the tables. Until this is done, the old company can hardly expect to wipe out its young rival, for stock quotations, like buckwheat cakes, are preferred hot from the griddle.

The Commercial Cable Company is another thorn in the side of the would-be monopolists. It is perhaps the only concern of the kind which has ever advertised in the *Herald.* It is also appealing by various striking methods, to the eyes of the passer-by on Wall street. Upon an ornamental cast-iron post at the corner of Broad, a gilded globe, apparently four feet in diameter, and appropriately lettered, has been erected as a clock, which is now externally illuminated at night by an arc lamp a short distance away, but in the dim future it is expected that three incandescent lamps at its base will perform this duty. In order to relieve all suspicion of British influence, which is associated with submarine cables, the globe is surmounted by a gilded eagle gazing on the statue of George Washington in front of the Sub-treasury. One of the Commercial cables, which was broken, has recently been repaired, and both are now in operation.

In my July correspondence, writing of the field which existed in this city for the introduction of electric motors, allusion was made to the use of a Sprague motor in driving a fan for ventilation of the Western Union operating room. The experiment was successful, and the improved condition of the air was highly appreciated by the operating force. The fan has been removed, doubtless for financial reasons. Either this or a similar device should be put in use at once, as the vitiated condition of the atmosphere in the room has been a growing evil since the occupation of the building, as the force in the office has increased. The gallery occupied by the commercial news department is perhaps worse than any other part of the room; but every portion is bad enough. This state of affairs should not be permitted to exist a single week. So long as it was an unsolved problem there might have been an excuse for refraining from the expense, but such is not now the case.

Electric lighting is gradually pushing its way into the conservative state of New Jersey. An Edison isolated plant of 250 lamps has been placed in the exposition of the Phil. Kearney Guard, Co. C., at Elizabeth, and another of 600 lamps in the Temple Rink. Pope, Sewall & Co. have also secured a sufficient number of arc lamp subscribers to warrant them in constructing a Schuyler plant, which will be in operation before the days begin to lengthen. A company has also obtained permission to exhibit its system of street lighting at North Plainfield, with a view to its final adoption by the authorities.

The American Telephone and Telegraph Company has applied for permission to erect a line of 45-foot poles in Bayonne, from the Kill von Kull to the Morris Canal.

The Metropolitan Telephone and Telegraph Company has just laid a new seven-conductor kerite cable across the North river, from the foot of Cortlandt street, New York, to York street, Jersey City. As the shore end of a former cable was destroyed by the fire on the Red Star wharf, the new cable terminates at the cable-house, instead of being strung along the pier as before.

A war of words is being carried on between the rival manufacturers of what is known as "underwriters" wire for electric light construction. The proclamation of one party gives rise to a counter effort of the other, the object being to frighten purchasers by the old-fashioned country threat of "taking the law of them." The manufacturers on both sides are, however, ready to guarantee purchasers of their wares against loss, so the users of wire may pursue the even tenor of their way.

The advent of the new special delivery "h. l. h." postage stamp was marked by no greater excitement than a tinge of curiosity to see what it looked like and how it worked in practice. The blundering old lady was on hand as usual to request the clerk to tell the carrier who delivered her letter to accompany it with a certain verbal message which she had forgotten to put in her missive before posting it. The man who puts on the h. l. h. stamp without the ordinary G. W. accompaniment, and expects his letter to be delivered p. d. q., has also discovered that the system is a delusion and a snare. With district messengers for a reasonable distance at 10 and 15 cents for local purposes, and a telegraph service at about the same figure, to points 250 miles away, either by day or night, the field for the latest postal experiment is not altogether a promising one. It has a mission, however, as it may lead to the possibility of insuring the delivery of letters the same day mailed in the morning to such cities and towns as are within three hours of New York by rail. This applies, however, to lengthy communications or papers of value, and in many cases it will compete with express as well as telegraph companies. Ten-word communications will still go by wire. The postal service has been gradually improving for years; but its chief excellence, like that of the telegraph, is far more appreciable for long distances than for local use. An institution which carries THE ELECTRICIAN AND ELECTRICAL ENGINEER, for instance, 3,000 miles to San Francisco and delivers it by carrier for half a cent, while charging two cents for delivery in the city of its publication, is certainly open to the charge of inconsistency.

Thomas A. Edison has notified Professor Robert Thurston, the director of the Sibley College of Mechanic Arts of Cornell University, that he proposes to present the school a complete electric-lighting plant for the new workshops and the mechanical laboratory. The university has accepted the gift.

CHICAGO.

Gleanings from the Berlin Conference.—Telegraphing in Theory and in Fact.—The City Fathers Propose to Investigate Underground Permits.—The Schuyler Company Preparing to Start Up on State Street.—Estimates Wanted for Lighting the River.—Arc Light Competition in Milwaukee.—Proposed Extension of Electric Lighting in Chicago.—Improvements in the Hanging of Lamps.

ON the occasion of the late international telegraph conference at Berlin, in honor of the event a special meeting of the electrotechnic society was held.

The president in a speech of welcome said, that "for telegraphy there is neither time nor space," and spoke of the pleasure, even to the habitual receiver of despatches, "when the telegraph brought news from the uttermost regions of the globe; or, when

Digitized by Google

these told of astronomical discoveries brought from beyond the seas within the space of a second, and finally, when we consider it within the range of possibility that in the future, thanks to electricity, we may be able to recognize the voice of friends separated by vast expanses of territory. This," he continued, "is the ultimatum of which this conference is the forerunner."

He congratulated himself and his hearers that Germany was the cradle of the electric telegraph. This fact, which marks a red-letter page in the history of the nation, should be to Germany a powerful incentive to develop by all possible means the activity of the savants of an institution representing the nations of the civilized world. Among the numerous problems which the study of electricity and electro-technics presents, is the great question of electrical phenomena in their bearing upon telegraphy.

The following resolution, introduced in the conference by M. Curchod, chief of the international telegraph bureau of Berne, adopted at the seance of August 13, explains itself:

"The international bureau of Berne is authorized, when occasion arises, to publish such statistics of atmospheric electricity, storms, lightning rods and terrestrial currents, as may be required by deliberations of the international conference, for the determination of electrical units."

The resolution renders the establishment of a centre of information for the prosecution of important researches possible, something which has heretofore been sadly wanting; while discoveries and theories in this line will hereafter not only be given to the world of science in a tangible form, but such data will be collated and recorded where it will be ever available to the world of progressive science.

There is something in the welcome alluded to above, however, which appeals to a sense of the ludicrous in the mind of the average operator. It will be yet a long time before the learned professor will be enabled to recognize the voices of loved ones at such distances as are here theoretically given. At the present writing such recognition is no dead sure thing two blocks round the corner; and from the jolly way in which the speaker makes dots and dashes fly round the earth it is highly probable that his experience at an humble railroad station, where the operator was also switchman, waiting for an answer to a rush message, has been quite limited—and there have been instances nearer home where messages have taken as much time as the summer sun to cross one half of Paris, which when delivered might be astronomical or religious, Hebrew or Choctaw, as far as the ordinary citizen could ascertain. This girdling-the-earth-in-forty-minutes business is all very pretty in poetry, but it don't average up well at tariff rates of so much a word.

Our city fathers are about to investigate the matter of permits as between the underground companies and the electric light people. In the session of the 12th the following preambles and resolution of inquiry were adopted:

"*Whereas* on July 31, 1882, page 97, Council Proceedings, an ordinance was passed granting to Henry Corwith and others, their successors or assigns the privilege of constructing and operating an undergr und conduit for electric wires in the streets and alleys, which said franchise is now held by a corporation known as the Chicago Sectional Underground Conduit Company, that section 5 of said ordinance provides that other persons shall be allowed to use said conduits, after being duly authorized by ordinance; and,

"*Whereas*. It is reported that said conduit company has allowed parties to use said conduits without such parties having first obtained the consent of this Council by a proper ordinance, while it has excluded others who are desirous of securing its benefits and willing to pay for the same; that said conduit company has granted to persons the right to dig up the streets for the purpose of laying electric wires on permits issued to said company for its own use by the department of public works, all of which are in direct violation of the spirit and letter of said ordinance; and,

"*Whereas*, Said conduit company has failed to appreciate the fact that a most valuable franchise was granted to it by the city, in that it compelled the city to pay a bonus of $10,000 for the privilege of providing for its wires: It is therefore

"*Ordered*, That the law department be and is hereby directed to cause an enquiry to be made as to the above facts bearing upon the violations of said ordinance, and to take such action toward the forfeiture of said franchise as the value of the evidence will warrant, with the view of obtaining for the city the privilege of using said conduits without cost, and to secure the money paid by the city for such privilege, and report to this council what action it has taken in the premises."

The Schuyler Electric Light Company, which is endeavoring to open up a plant on either side of State, between Madison and Monroe, requires a permit to cross State. At the same meeting an ordinance to this end was offered, and after some slight skirmishing, referred to the Fire and Water Committee. At the same meeting the city electrician was directed to furnish estimates for lighting the main river, and the north and south branches, from Kinzie to Harrison street.

Two competing companies from here—the Sperry and the Badger—are pestering the Milwaukee people for a chance to introduce arc lights in that city.

On the same evening that our municipal fathers were working on electric lighting here, the solons of our sister city were also wrestling with similar matters. At the meeting two weeks previous, an ordinance was passed by a vote of 25 to 14, permitting the Badger people to erect and maintain plants, and run wires overhead in certain localities, while it required the company to place its conductors under ground in other portions of the city. But the bridge which had brought the company safely over the chasm thus far had still one uncertain plank, and this failed when the procession reached the spot. The ordinance was vetoed and—curious coincidence—the vote on the proposition to carry the ordinance over the head of his honor stood as on the previous vote, 25 to 14, although there had been some changes among the members. One more in its favor would have made the necessary two-third vote. Then came an ordinance in favor of the Sperry company, which now takes its chances, while an amended Badger ordinance is also listed for the race, and the pro and con petitions and remonstrances from the good people of Milwaukee are strewn as thick as leaves in Valambrosia, or, perhaps as more appropriate in this wooden country, as slivers in a lumber yard.

There was sharp word shooting in the debates on this august occasion, and the probability is that at the next regular convocation of the council there will be like Smith's razor strops, "a few more left of the same sort."

Electric lighting is to be rapidly extended over the north and west divisions of Chicago. Arrangements have been completed by which central plants will be extended over those districts at once, and the Dorsett conduits will be availed of by a new organization which promises to do thorough and complete work over large areas of territory. Enough experimenting has been done to convince those who desire to install this species of work that the best is the cheapest in the long run, and that while the original outlay to ensure the most satisfactory results dips deeper into the pocket, the subsequent account for maintenance is much less, and really more economical.

Heretofore there has been much annoyance arising from the unseemly and awkward system of hanging outside lamps. A plan recently submitted, which has so far no objectionable features, is to be put into service at once, as an experiment, and if this works as well as it is believed it will by those who have seen it in sketches it will do away with the objectionable clothes-line loops, relieve the halyards of the strain to which they are now subjected, and at the same time permit of the raising and lowering of the lamp, bringing it in the latter case to a portion of the walk out of the path of pedestrians. We shall see.

CHICAGO, Oct. 17, 1885.

PHILADELPHIA.

The Western Union and Bell Telephone Companies Decide to put Some Wires Underground.—President Bentley says Subterranean Service will be Limited.—New Quarters of the City Electrical Department.—Detrimental Effects of Abandoned Aerial Wires.—Litigation Regarding the City Pole Tax.—The "Novelties" Exhibition.

AN ordinance was passed at the last meeting of councils authorizing the Western Union and Local Telegraph and Bell Telephone companies to put some of their wires underground. President Bentley said recently that the move might be regarded as a step on the part of those corporations towards eventual compliance with the ordinance directing that all the city wires be run through subterranean conduits. There would not be time between this date and the 1st of January, 1886, to put all the wires underground, but the completion of the plan now contemplated would give ample opportunity for ascertaining definitely whether subterranean telegraphy could be made a commercial success, as it was designed to have the work finished in time to allow of a thorough test of the working of the wires during the coming winter. The period, however, when all overhead wires would disappear he considered quite remote. It was only in the heart of the city and within a circumference including comparatively not a great many blocks that the trouble with the overhead wires manifested itself. For distant sections, and further out still, in the suburbs, the wires were so scattered that no inconvenience was experienced from having them overhead, and in such localities they were an absolute necessity.

No company, indeed, would consent to extend a conduit system beyond very restricted limits, as the outlay would be ten times greater than the income, and suburban residents, instead of being able to have telephones connecting their homes with their places of business in the city, would simply be informed by the telegraph people that they must decline to incur the extra expense. That the people themselves might choose to combine and put down conduits leading to their homes, president Bentley did not appear to contemplate; no doubt, on account of the expense attending that display of enterprise, and, therefore, he believed in the practical perpetuity almost of the overhead wires in more remote neighborhoods, as the telephone had become so important an accessory of American every day life, being used in this country to an extent absolutely unknown in Europe, and by people who, on the other side of the water, would consider electric communication a luxury far beyond anything their means would permit them to aspire to. French and even English electricians, he remarked, on coming to this country expressed themselves as highly astonished at finding the telephone as almost an article of domestic comfort and convenience, and assured him that with them it was so used only by the nobles or by wealthy manufacturers, and was still far enough away from being in anything like common use among the well-to-do classes at large.

Digitized by Google

Early in January next, chief David R. Walker, of the city electrical department, will begin to move into his new quarters in the public buildings. It will take at least a year for him to get settled, and he will have the finest electrical system in the world under his control. The wires used by the department all enter the buildings at the northeast and southeast corners, through two great tunnels, which extend to the curb, and will then be carried to the northeast tower. The operating, receiving and transmitting rooms and the office of the chief are on the fifth floor, the storage room is on the sixth floor and the battery room on the seventh. The wires will be carried up through a box in one angle of the tower to the rooms above mentioned, and the box will be large enough to contain a ladder, provided with convenient platforms, by means of which the wires can be examined and repaired at any time. The main operating room is 46x51 feet and it is connected with the office of the chief. At one end is a sleeping room, which will be used by linemen and operators who go on duty at midnight.

"When my new quarters are completed I shall feel very proud of them," said chief Walker. "I have adopted every practical idea that I could get hold of in their fitting up, and I think the electrical department of Philadelphia will soon be as well equipped and as comfortably and conveniently quartered as that of any city in the world."

The new system was thoroughly inspected yesterday by the chief, in company with William B. Gill, superintendent of the Western Union company in Philadelphia; D. Doren, general superintendent of construction for the Western Union, and a party of newspaper men.

Every time a storm, such as that which prevailed in this city a few days ago, occurs, telegraphic and telephonic communication between different points in the city is greatly interrupted, and business men experience great inconvenience in transmitting despatches. "A great deal of this trouble," explained chief Walker of the electrical department, "is due to old, abandoned wires breaking down during the storms and falling on the others. Several years ago various telegraph and telephone companies strung their wires all over the city on housetops or anything else that they could fasten them to. Many of them were put up purely for speculation, and they are of poor quality and badly strung. Other companies lost their franchises in the courts and were compelled to abandon the use of their wires. The disused wires have become rotten and every time there is a storm many break and cross the working wires, causing great confusion. The trouble will continue until they are removed.

There has been a consultation between counsel for the various telegraphic companies in this city, relative to the order recently issued by Judge Hare for a re-hearing of the case of the City *vs.* the Western Union, Mutual Union and Bell Telephone companies, which was an action to recover license money for privileges. The referee in the case originally decided that the city's charges were unreasonable, and his report was confirmed by Common Pleas Court, No. 2, June term, 1883. By this decision the city would lose about $15,000 per annum. The superintendent of the electrical department, however, has since appealed to the Supreme Court, and the case will be heard again. The United States court, sitting at New Orleans, recently decided in a similar suit that the city could charge $5 per pole if it liked, whereas the charge in Philadelphia is only $1 per pole.

Although the Novelties Exhibition is doing quite well as far as the daily and nightly attendance is concerned, I fancy the average will not come up to that of the electrical exhibition held last year. Outside of dynamos and electric lights, there is little to be seen at the "Novelties" in the "electric" line, still it is a very interesting place for one to go.

The board of judges who will award the premiums and diplomas has been organized and is ready to begin work. The exhibits have been arranged into 21 classes. The first premium is a silver medal with a diploma, the second, a bronze medal with a diploma, and the third a certificate of honorable mention. There will also be awarded a medal of honor to the invention which shall be decided to contribute most largely to the welfare of mankind. It is hoped that the reports of the judges will all be presented before October 20th.

PHILADELPHIA, October 19, 1885.

SAN FRANCISCO.

Improvement in the Telegraph Service.—A Subterranean Cable to be Run Along the Snow Sheds.—The Electrical Exhibits at Mechanics' Fair.—Electric Light Rivalry.—The Supervisors Object to Additional Poles in the Streets.—Extra Operators Employed by the Western Union.

THE visit of Col. Clowry and his able lieutenants, C. H. Summers and M. C. Bristol, to the Pacific coast has been prolific of the most beneficial results, indeed a trip every six months would work untold wonders in expediting business. The southern lines which previously were of no benefit to San Francisco as an outlet for business now work beautifully, and indeed it is a pity we have not such a wire to Ogden. Mr. Summers will stand no fooling, he knows the capacity of a wire and expects it worked accordingly, and to insure this has reports of the day's business sent to him every morning to Chicago, hence if the middle route is "gone" we are not completely isolated as was the case many a time previously.

We are to have a seven conductor double armored cable laid between here and Oakland, and also a cable to be laid underground the entire length of the snow sheds across the Sierra Nevada summit on the Central Pacific. These are both wise moves, and it is to be hoped the Oakland cable will be laid from a point out of the way of dragging anchors, which invariably bring trouble when we are treated to a strong south-east wind, once or twice a year. A snow slide carries all before it over the mountains where the snow sheds are built, and a cable there will insure us telegraphic communication, when all else fails. Bristol's quick eye saw this and supported supt. Jaynes in his request for the cable which was allowed. Col. Clowry, Mrs. Clowry, Miss Estabrook, Messrs. Summers and Bristol occupied the Western Union car "Puck," and the ladies particularly were enchanted with California. The Mechanics' Fair has just closed. The electrical exhibit was the same as heretofore, but the various wares were tastefully displayed. The California Electric Co. was outdone by the Pacific Electrical Supply Co. in neatness and variety of electrical machinery and apparatus. Mr. Osborne exhibited the Stockwell sewing machine appliances and motor which attracted much attention.

The Thomson-Houston Electric Light Co. is waging a bitter warfare against the California Electric Light Co. (Brush) to obtain from the supervisors equal rights to erect poles in the streets or be allowed to string wires on the poles of the California company. The board is averse to permitting any more poles in the streets, and as P. B. Cornwall is the head and front of the California company, and being a very prominent politician, the chances are, the Thomson-Houston people will be "left."

The Western Union operators (with one exception) in this city resolved to refuse to do extra work without extra pay, and so notified the superintendent, who advised them to take no hasty steps, but to submit to him a statement of the case and he would present it to Col. Clowry, all of which has been done, and it has resulted, not in allowing extra wages, but in increasing the force two operators. Judging from appearances, I should say that while the operators are pleased with the prospect of lighter duties, they would prefer the "extra," as some have families, and could thereby earn a little more every month.

Mr. Leonard W. Storror has resigned the position of cashier, and his place has been filled by George Senf, of Virginia City, Nevada.

SAN FRANCISCO, Cal., Sept. 27, 1885.

BOSTON.

The Tribulations of New England Telephone Subscribers.—The Telephone as a Political Issue.—Increasing Use of the Judkins Train Signal.—The Serson-Welsh Battery.—A Peculiar Dynamo Accident.—The New England Meteorological Society.

THE New England Telephone Company quietly pursues its settled policy of raising the rentals throughout its territory. There is still fluttering and protesting on the part of the subscribers, but the wheels turn around just the same; many telephones have been taken out and many more put in, so the general average will be kept up. In one town all of the doctors agreed to allow their telephones to be taken out, and they were. Soon all of the doctors but one found out that the *one* had his telephone in good working order, and was scooping in all the sore throats and baby troubles in the neighborhood, so the rest, as a matter of protection, had to succumb and continue their acquaintance with the "hello" girl at the central office.

The thing works about like the above incident. If the rates were oppressive it would be quite a different matter. The general public look at their telephonic apparatus and think the whole outfit, line included, does not cost as much as they pay for their service in one year, and conclude that the telephone company must be making an immense amount of money; quite forgetting the cost of maintenance, the liabilities incident to the business, etc. This kind of an argument would not suit, say the doctors mentioned, if a patient should complain of his bill for services, and conclude, as the prescription did not cost but half a dollar, the doctor must be making money to charge $2.50 or $3 for a visit. I had a conversation with a telephone subscriber recently, who was grumbling because his telephone services cost his office $120 a year, with the privilege of talking with 5,000 people, and with many more at a slight advance, and asked him how much he used to pay for an errand boy. He said $3 per week, or $150 per year. And yet was a "kicker" because he got more service for less money.

According to present indications, the local telephone matters will furnish plenty of excitement for our next legislature. The parties are now nominating candidates for the new legislature, and the "New England Telephone League," by its represent-

Digitized by Google

atives, appear at the nominating conventions and submit a circular and resolution, as follows:

BOSTON, MASS., Oct. 3, 1885.

DEAR SIR:—We very much desire that in every senatorial and representative convention a resolution similar to that following this note may be passed. In several legislatures laws limiting the charge for telephones to $3 per month have been passed and are in force. All over our state, except in the Cape district, telephone rates have been, or are to be, raised, and the entire commonwealth is in a turmoil over the uncalled for advance. The American Bell Telephone Company, having only $550,000 actually invested in telephones, is paying out in dividends over $3,000,000 annually. The spectacle of the business and professional men of the state paying a tribute of 750 per cent. (this is the exact rate) is an humiliating one. Respectfully,

NEW ENGLAND TELEPHONE LEAGUE,
P. O. Box 2567, Boston, Mass.

Resolved, That this convention is opposed to the present telephone charges imposed on the people by the telephone monopoly, and urges the General Court, at an early day, to fix by la w the rates which telephone companies shall be allowed to charge within this state.

They evidently mean business, and propose to have an anti-Bell telephone "general court" if they can.

The Judkins Electric Signaling Company are pushing their apparatus, a substitute for the bell cord on railway trains, very extensively. They have just contracted with the Boston and Maine Railroad Company to equip all of their passenger cars and engines. The railroad has in use over 200 engines and about 500 cars. The Judkins signal is highly recommended by all the railroad officials using it.

The Serson-Walsh reservoir battery has been put on the market, with substantial claims for merit. It is an open circuit battery, but the inventors say it will work on a closed circuit longer than any in use. At the Boston and Albany railroad depot, on the gong circuit, two cells did the work of 10 Leclanché cells. The inventors further say it will last 12 to 18 months without renewal or attention, keeping itself clean, and is self-feeding. It is tightly sealed, and made for train signals, bells, etc.

At the Grinnell cotton mill at New Bedford, on the 24th ult., an accident occurred while electric lights were being put in, graphically described as follows by the newspaper scientists:

"While workmen were putting in electric lights, under the management of F. B. Comings, of Dorchester, steam was turned into the dynamos, when the pipe burst, throwing Comings, together with superintendent Kent, of the mill, and the engineer, across the room and into a pit. The two latter escaped with slight injuries, but Comings was badly cut and scalded about the face, head and breast, perhaps fatally. He was taken to St. Luke's Hospital."

In view of such accidents, it is full time that dynamos were put underground.

The second annual meeting of the New England Meteorological Society, was held in Boston on the 20th. The following officers were elected—president, W. H. Niles; secretaries, W. H. Davis, D. Fitzgerald; treasurer, E. B. Weston; director, W. Upton. A report of the first year's progress and work was read by Mr. Winslow. Among other achievements the society has succeeded in introducing the signal flag service in over 100 towns in New England. Mr. W. M. Davis read a paper on "Thunder Storms in New England in the summer of 1885." Over 450 observations had been sent in from society observers who are well distributed over New England. The speaker then described the nature of a thunder storm and the atmospheric influences which preceded it.

BOSTON, Oct. 20th, 1885.

ELECTRICAL NEWS AND NOTES.

THE ELECTRICAL SUBWAY COMMISSION.

The resumption of the sittings of the Commission on September 29th, after a recess of two weeks, was marked by a larger attendance than usual. An application from the president of the Metropolitan Telephone and Telegraph Company was read, for permission to construct a conduit for its wires from the corner of Wall and Water streets in this city to 180 South street, near the East river bridge. The construction of the conduit is to be of a similar pattern to that already put down by the same company in 39th street, which is a box made of creosoted wood through which cables are drawn. From Wall street to Fulton it will contain 150 wires, and from Fulton northward to 180 South, 300 wires. This subterranean structure is intended to supersede two lines of poles carrying 185 conductors, and as they are now overloaded, the company is anxious to complete the work before winter sets in.

Action upon this proposal was postponed until the next meeting.

A letter was read from the board of fire commissioners, stating that no permission had been granted to electric lighting companies to place their wires upon the poles of the fire department, but that in some instances attachments had been made at crossings, in order to avoid any liability to contact by the sagging of wires.

Daniel Moore submitted the plans of Captain William Mackintosh, the inventor and patentee of a system to which he had devoted much thought, and it was the outcome of many years of practical experience. Under his patents of January 20, 1874, he claimed the exclusive right for laying down sectional cables, terminating in alternate working chambers. Such chambers or manholes are to be connected by iron or earthenware pipes in lengths of from 12 to 25 feet, these pipes being imbedded in plastic material. The estimated cost of a system of this character was less than $10,000 per mile. It permitted the drawing in and out of such cables as might be adopted by the various electrical companies. It had been submitted to different corporations, who made no objections to any of its features, and some of them had entered into negotiations for its use. The advantages claimed were:

1. That the water, sewer, gas and steam systems present no insurmountable obstacles to its adoption.
2. Ready access to the wires placed in it.
3. The cost, if not less, is no greater than that of any practical system.
4. Its durability is unquestioned, and the system is of an expansive character readily accommodating itself to the future growth of electrical service.

Mr. Moore stated that it was not in practical operation.

Mr. Shelbourne disputed the broad claim made in behalf of the Mackintosh patents, that they covered all systems embracing working chambers connected by pipes, such features having been used in Europe for 30 years. The patent was what is known as a combination patent, the only novel feature being the so-called comb which it was proposed to use in connection with the conduit.

Mr. Moore replied that the owners of the patent were fully prepared to defend their rights.

David Brooks, of Philadelphia, in presenting his system, stated that in the event of its adoption he was authorized by president Norvin Green of the Western Union Telegraph Company, to say that a construction company would be immediately formed, and the work pushed forward in the shortest possible time. There were four miles of his system laid in Europe, a short piece having been put down in Belgium in 1879. That had been subjected to the severest tests, and its insulating qualities had not deteriorated. All work done abroad had been guaranteed. There was no system in Europe which permitted single wires to be drawn out and replaced. It had been shown by experience that in doing so, other separate wires were damaged, and therefore it had proved to be more satisfactory to draw in or out an entire set of wires at one time. For telephone work, 400 wires had been placed in a single pipe in New York city. On Mercer street there was a splice box every 45 feet. In Philadelphia 2,000 feet had been put down in a single day along Front street, the trench being dug, pipe put down, and street repaved. It was the cheapest of all systems. [A fully illustrated description of the Brooks system appeared in the ELECTRICIAN AND ELECTRICIAL ENGINEER, November, 1884.—EDITOR.]

Mr. Jaegel presented a new model of his street railway conduit, in which a cast-iron subway formed the foundation for each rail of the track.

On Thursday, October 1st, Sidney F. Shelbourne stated that three years had elapsed since the incorporation of the New York Electric Lines Company, which, as indicated by its name, was not for any special branch of electrical service, but to furnish lines for the use of all systems. During this period his entire time had been devoted to this subject. His company had not only a system, but patents covering that system. In April, 1883, the company obtained a franchise for putting it down in the streets of New York, by the terms of which two per cent. of the gross receipts were to be turned over to the city. The companies made the plea that they could not continue their business if compelled to put their wires underground, because they would not work. He presented a sample of the cable which his company proposed to use, which, he said, was the only cable in the world which would nullify dynamic induction. The Metropolitan company ordered 6,000 feet of this cable to put up overhead, and last spring it was connected with the Spring street exchange. So far as tested it had proved satisfactory.

A conduit is simply a hole through the ground. When the pipe is made of an insulating material, induction cannot be prevented. He had come to this conclusion, that the best, the simplest, the most durable and the most reliable article for this work was cast-iron pipe. The pipe, according to his plan, was not made round, as a tube of this shape would not permit a sufficient number of cables to be drawn through to economically utilize the space. It was nearly oval in shape, with straight perpendicular sides, and rounded at the top and bottom. In this the cables could be more readily drawn parallel to each other, the first layer of three filling it up to the beginning of the straight sides, which confined the subsequent layers to their proper amount of space, instead of permitting them to run from side to side as was the case in a round pipe where the increased width gave annoyance in that way. In every second street would be placed a manhole, which was a cast-iron box with a sealed cover, and gas-tight. His company owned what he called a cable carrier, by which cables could be readily placed in a conduit without the

Digitized by Google

slightest injury to them from abrasion. Old cables could also be readily underrun and removed by the same means. For the distribution of wires he had devised an ornamental cast-iron post, one of which being located at each block, the wires were led up through it by a small lead-covered cable to the adjacent roof and thence to the rear of the buildings as required, or if preferred they could be carried underground through the cellar walls.

Mr. Shelbourne continued his remarks at the session of October 2d, when he presented a different pattern of conduit in which an iron pipe about eight inches in diameter was filled with two inch tubes imbedded in cement, the tubes being first dipped in coal tar, and were to be in three feet lengths. Such a pipe with 20 tubes would cost from 75 to 80 cents per foot. The largest lead covered cables made by any process excepting his were from ¾ to ⅞ of an inch in diameter. Cables were usually either of kerite or gutta-percha wires wrapped and drawn through the conduit. The Western Union company had undertaken to draw through plain gutta-percha cables in their Broadway pipe, and had gone as far as Grand street, but they had stopped on account of the steam heat melting the gutta-percha insulation. The vice-president had informed him that as soon as he could furnish a cable it would be adopted. Mr. Shelbourne closed his presentation with an explanation of his very ingenious plan of numbering and connecting wires in the manholes.

On October 7th a plan devised by George M. Cushing, of Boston, was presented by his attorney, which was a conduit to be constructed of vitrified earthenware in the form of a trough, to be placed under the gutters with covers at suitable locations, the joints to be strengthened by brick abutments, and the whole covered with bluestone flagging. Connections with the sewers are to be made at the lowest points to facilitate drainage. The estimated cost of a conduit of this pattern, 4x3½ feet, was $3.30 per running foot. No provision was made for the separation of the different services.

On October 8th E. H. Austin exhibited samples of the conduit proposed by William Redde, which was patented in 1873, and put down for exhibition purposes at the Centennial Exposition at Philadelphia. It consists of small glass tubes imbedded in an insulating composition or plaster-of-paris within a wrought iron pipe. These tubes are intended for the accommodation of bare copper wires, and may be furnished in lengths of 10 to 15 feet. Mr. Austin stated that at the time the Gold and Stock Telegraph Company moved its operating room from 61 to 197 Broadway, he offered to make a very liberal arrangement and guarantee the working of the wires underground if the company would adopt this system, in order to give it a thorough practical test. The company, however, did not wish to demonstrate the feasibility of subterranean work, and consequently his proposition was rejected.

October 9th the Hastings Pavement Company announced that in case a conduit of masonry was adopted, the blocks composed of asphaltum and limestone, moulded under heavy pressure by that company, was a desirable material for the purpose.

Mr. Anderson, in behalf of the Metropolitan Telephone and Telegraph Company, said that in a letter dated September 24th, that company applied for permission to construct a conduit, and it was desirous to place its wires underground. The pole lines were overloaded, and in order to insure the effectiveness of the service they must either be rebuilt or the wires placed underground temporarily if not permanently. The company desired to retain such poles only as were necessary for the distribution of wires to subscribers. As Mr. Anderson was unable to state just how many poles would be required for that purpose he was requested to notify the Commission in writing exactly what was proposed, when the matter would be taken into consideration.

October 12th T. A. B. Putnam, of the Railway Cab Signal Co., 40 Broadway, presented the plans and specification of his cast-iron conduit, which is to be in the form of a bisected pyramid, divided into compartments by iron partitions running longitudinally through the structure. In the sketch as shown there were four of these, making five spaces in all. A conduit of this pattern, 24 inches in width at the base, 12 inches at the top and 24 inches high, would accommodate 5,000 wires. The top compartment would contain light and power wires, the next below it fire alarm and district, the next telegraph and quotation, while the lower two would be devoted to the telephone service. Each class of wires being surrounded by a metallic wall abutting on the earth at each side, the inventor claims that they would be entirely free from interference excepting that arising from wires of their own class. The conduit would be provided with manholes, and a distribution pole made with five longitudinal compartments would be placed every 500 feet. The cost of a conduit of this character, accommodating 5,000 wires, would be about $44,000 per mile. Its advantages are claimed to be, freedom from induction, facility for handling wires, and the low cost per mile of wire.

Geo. B. Pennock offered what he believed to be the cheapest practical system, by which he would undertake to put down all the wires in the city for $500,000.

Marcus Marx submitted a sample of pipe for underground work made of 1¼ turns of sheet iron, upon the inside and outside of which was a heavy layer of asphaltum. It could be supplied at half the cost of iron pipe.

On October 13th the Standard Underground Cable Company, of Pittsburg and New York, made a fine exhibit of samples of their various patterns of the Waring lead covered cable.

Mr. R. S. Waring, vice-president of the Standard Company, opened the hearing in the following words:

"GENTLEMEN: The Spartan mother, in response to the question 'Where are your jewels?' pointed to her children and said 'These are my jewels.' So we point to these specimens of handiwork representing the Standard Underground Cable Co.'s system of electrical conductors, and say, 'These are our jewels.' They have stood the test of time. I prefer, however, that the explanation of the system, the merits claimed for it and the results attained, as shown by the satisfactory working of the cables laid, should be left to those less interested than myself, but who are thoroughly capable of presenting the subject fully and fairly for your consideration. With your permission, gentlemen, I present to you Mr. G. L. Wiley."

[An illustrated description of the Standard Underground cables will be found in the ELECTRICIAN AND ELECTRICAL ENGINEER, December, 1884.—EDITOR.]

Mr. G. L. Wiley said: I have the honor to present a statement and drawings of the underground cable system of the Standard Underground Cable Company for telegraph, telephone and electric light uses. The insulating material used by this company is a hydro-carbon compound of very low specific inductive capacity and the highest attainable insulating qualities—in fact, very much in excess of that practically required in the working of any telephonic, telegraphic or other electrical system. From actual measurements made by Mr. Frank L. Pope for the New York Fire Department on cables of our lightest insulation, the insulation resistance was found to be 946 megohms per mile. The insulating compound being an inorganic substance, there is thus no reason to anticipate any deterioration from time and use, and this has been abundantly proven by the results in the cables of this manufacture longest in service.

Even so good an insulator as gutta-percha cannot be handled without danger at a higher temperature than 100 degrees Fahrenheit, while at a temperature of 112 to 126 degrees paraffine melts. Now, the heat in the steam-heating pipes must be above the boiling point of water (212 degrees), and a temperature much lower than 212 degrees will vaporize paraffine and destroy the usefulness of gutta-percha and most other insulating materials. The vaporizing or carbonizing point of our insulating compound is extremely high, so that cables, the conductors of which have been treated with this compound can, with entire safety, be laid in close proximity to steam heating pipes (a rare and important advantage), especially in New York city, where so many steam-heating pipes are already in use in the principal thoroughfares, and where at any time additional pipes are liable to be laid alongside of existing underground cables.

The Waring Anti-induction Cable.—The Waring anti-induction cables are manufactured in many forms to suit a variety of uses, and may contain any required number of conductors; but whatever the form, the general principle of construction is substantially the same in all. The conductor is first enveloped in a wrapping of fibrous or textile material, which is then saturated and coated with our insulating compound, to which the name "ozite" has been given, and the whole is afterward inclosed in a continuous sheathing of lead, which is pressed closely around the insulated conductors, each conductor being separately surrounded by the metal on all sides. This metallic sheath serves to perfectly screen each conductor from all induced currents from adjacent parallel conductors, making it the only absolutely anti-induction cable and the only cable in which telegraph, telephone and electric light circuits may be worked side by side without interfering the one with the other. The disastrous effect of induction on telephone circuits is so well known that no elaboration is needed. In the Waring anti-induction cable the inductive action from wire to wire is, of course, effectually cut off by the intervening shield of metal, a feature which renders the cable peculiarly well adapted for the telephone service. But not only does the construction of this cable prevent interference from induction in the cable conductors themselves, but also where air-lines are connected to even a short length of the cable the latter is found to eliminate induction.

No underground cable that does not embody this anti-induction feature is adapted for a general underground system, in which telegraph, telephone and other electric circuits may be worked in the same cable.

Branching and Looping.—In any general underground system facility of branching and looping is an important requisite, and this is a special feature in the Waring anti-induction cable. It will be observed that one of the exterior ridges of the cable (sample shown) is somewhat different in section from the others, being provided with a sharp edge or corner which serves to designate the position of one particular conductor throughout the entire length of the cable. The position of one conductor being known, enables the position of any one of the others to be readily

Digitized by Google

determined; the principal object of this arrangement is to enable a branch or loop to be inserted into any one of the conductors of the main cable without disturbing the others. The way in which this loop is inserted into the cable will be understood from the samples exhibited; the branch or loop itself is usually a two-wire cable divided at the end for a short distance, as shown, and its conductors spread apart and attached to the severed ends of one of the conductors of the main cable which has been previously opened for the purpose, after which the lead coating is made continuous by a soldered joint similar to that employed in fitting up water pipes.

The cables are made in continuous lengths in the factory, and are divided into suitable pieces, for convenient handling in transportation and laying, and the ends of the sections are united when laid by a simple and efficient joint or splice.

Compactness and Flexibility.—For trunk lines and general street service 2,000 to 8,000 of these anti-induction cable wires (according to the style of cable used) may be laid in a box one foot square. Any of the forms of cable shown above are specially adapted for this purpose, as they are very flexible, are easily and quickly handled, and will pack in a small compass, and their flexibility prevents all injury from the settling of the earth from the effects of frost or from other causes. By using the style of cable shown (an eleven-wire double flat cable), fully 8,000 conductors can be placed in a box or conduit one foot square.

The Waring Bunched Cable.—The Waring bunched cables, are made for telephone and telegraph uses, and any desired number of conductors, up to 100, may be bunched together and covered with a single metallic sheath or lead pipe. In these cables the same high insulation is secured, but the facility of branching and looping, and the entire freedom from induction, are not attained in such perfection as in the Waring anti-induction cables just described.

Electric Light Cables.—The Standard Underground Cable Company manufactures cables of different styles and containing various sizes of conductors and thickness of insulation, both for arc and incandescent electric lighting. (Samples were shown containing conductors composed of strands of smaller wires; their high insulation and non-liability to injury from heating render them peculiarly well adapted for carrying the heavy currents required in arc lighting.)

Conduit.—Many conduits have been invented through which it is necessary to draw the electric cables after the conduits have been laid and closed; but the majority of them seem too expensive for practical use, and there is always danger of injuring the cables in drawing them into the closed conduit. A very inexpensive and serviceable conduit can be made of hard yellow pine with a lifting cover to give easy access to the interior. A conduit of this nature, measuring one foot square inside, would hold from 2,000 to 14,000 conductors. It may be objected that the cables should be easily accessible without again tearing up the streets for branching, looping or increasing the plant. In order to provide for such contingencies, a sufficient number of manholes can be established to answer all purposes of branching and looping, and the low first cost of this simple conduit will permit a saving sufficient to enable the various companies, when laying the conduit or box, to anticipate and provide in advance a sufficient number of conductors for their future needs.

Laying.—The practice in laying this cable has been to dig the trench not over two feet deep, and sufficiently near the surface to avoid gas and water pipes, a foot or two outside the curb; lay the pine trough or box in the bottom of the trench; drive the reels, mounted like hose carriages, along, paying off the cable into the conduit as they move, filling any vacant space in the box with pitch or with earth packed solid; then fastening down the top of the box and filling in the ditch. Not more than one street block needs to be opened at a time, and the work can be very speedily done without interfering seriously with general travel.

Durability and Freedom from Interruption.—Aside from mechanical injury, the length of time which lead will last may fairly be taken as the lifetime of the cable. The cable is not subject to the destroying influences of wind and sleet storms, nor to electrical storms, and communication is never interrupted. Once laid in the earth, it needs no further attention, and the outlay of 20 per cent. per annum required for repairs and renewals of air-lines is entirely obviated.

The workmanship of these cables is of a high standard of excellence; the company's patented processes insure such a high degree of mechanical perfection in its cables as is not attainable by any other process, and every piece of cable, before leaving the factory, is carefully tested, inspected and approved by the electricians in charge. The successful working of all the lines which have been laid by this company is a sufficient evidence of the watchful care which has been exercised.

These cables are no longer in the experimental stage; they have been thoroughly tested for over three years, and up to this time have never failed.

The underground cables of this company are in successful use by the Municipal Telegraph and Telephone Department and by the National Government Departments in Washington city, the Baltimore and Ohio Telegraph Company, the New York Fire Department, the Municipal Telegraph Department of Philadelphia, the telephone companies of Pittsburg and Chicago, the United Lines Telegraph Company, and by the Union Switch and Signal Company, and others on railroads, and in many mines throughout the country, etc., etc.

To summarize, we claim for the underground cables hereby presented:

1st. Extremely high insulation and very low specific inductive and electro-static capacity.

2d. Freedom from induction.

3d. Elimination of induction on through circuits composed partly of air-lines and partly of cables.

4th. Greatest facility of branching and looping.

5th. Ease and rapidity of laying underground.

6th. Compactness and flexibility.

7th. Durability and freedom from interruption when once laid.

8th. The mechanical protection afforded by the lead covering.

9th. Perfection of the mechanical work.

10th. They have stood the test of time.

In conclusion, and in corroboration of what we claim for our cables, we beg to refer to the letters and reports of tests contained in the pamphlet herewith submitted; reports made both by practical and scientific men, many of whom are of national reputation, and many of whom use these cables daily in the transaction of their business.

Among others, who are to-day practically using our cables, are the Union Switch and Signal Company, of Pittsburg, and the New York Fire Department. I understand Mr. Frank L. Pope, now present, is connected with the former company, and I would respectfully suggest that the Commission call upon Mr. Pope for a statement of his knowledge in the premises, and upon superintendent Smith, of the New York Fire Alarm service, also present, for a report of his experience with the Waring cable.

Mr. Pope, at the request of the Commission, stated that he is a director of the Union Switch and Signal Company, who have placed nineteen-twentieths of all the electrical railway signals and switching apparatus now in use in this country. After explaining the system used by the company, and the necessity therein for reliable wire service, Mr. Pope stated that they had experienced great trouble with all the different kinds of wire used until they began to use the lead-covered wire of the Standard company, which had proved entirely satisfactory. Mr. Pope also informed the Commission that he had made careful tests of the Waring cable for the New York Fire Department, which tests had shown a degree of perfection far beyond his expectations. The insulation of the cable, he stated, is of an inorganic nature, not liable to change, and in his opinion this is an essential feature of any successful underground system.

Mr. J. Elliot Smith, superintendent of the New York Fire Alarm Service, informed the committee that his department had used several sections of the Waring cable, varying in length from one hundred to eight hundred feet, for the past eighteen months, and the results have been uniformly satisfactory. The confidence of the fire commission in the reliability of this cable is proven, he said, by the fact that they are about to place all their circuits, 170 in number, underground by this cable, from headquarters outward for several blocks in each direction.

Following Mr. Smith, Mr. W. J. McElroy, electrician of the Standard company, addressed the commission for the purpose, he said, "not of explaining what his company might be able to do in the future, but to describe what they had already accomplished in the past."

Mr. McElroy stated that he had been connected with the Standard company from the earliest hours of its existence, and in his capacity of electrician was thoroughly conversant with all the work done by that company.

The first piece of cable made by Mr. Waring was laid between the Vesta and Brilliant oil refineries, on the Allegheny river, in the early spring of 1882. This cable contained five wires and was a little more than half a mile long. In the fall of 1882 this cable was continued on down to Pittsburg, terminating at a point on Duquesne way, eight miles from the Vesta refinery, the upper end of the line.

This cable worked perfectly for both telegraph and telephone work. Among others who were attracted to Pittsburg by the reported success of the cable, for the purpose of personal examination, and who are consequently well acquainted with the merits of this system, were Messrs. Frank L. Pope, of this city; W. H. Eckert, general manager of the Metropolitan Telegraph and Telephone Co., of this city; W. D. Sargent, of the Brooklyn Telephone Co.; T. D. Lockwood, electrician of the American Bell Telephone Co.; George T. Williams, superintendent for many years of the Western Union Telegraph Co., Cincinnati district; Prof. Dolbear, of Boston; superintendent J. Elliot Smith, of the New York Fire Department; Prof. John Barrett, city electrician of Chicago; Henry Metzger, general manager of the Pittsburg Telephone Co., and David McCargo, general superintendent of the Allegheny Valley Railroad. This cable was laid in the ground without box or other protection, and has suffered considerable damage at the hands of the natural gas pipemen.

The next work done by the company was in Washington city,

Digitized by Google

where, in the fall of 1883, they laid for the United States government a line of two cables connecting the capitol, Smithsonian Institution, White House, State, War and Navy departments, and the department of public buildings and grounds, the distance covered being over two and a half miles and the total wire mileage 32 miles. In addition, they laid for the district government a line of 12 wires from the fire-alarm headquarters to their No. 4 engine house on Virginia avenue, and a line of six wires connecting the headquarters with the district building on Four-and-a-half street, the total wire mileage reaching about 14 miles. All of these wires work well and are in daily use. Telegraph and telephone wires are used in the same cable, side by side, without the slightest interference.

The question of connecting air-lines with cable wires having been raised in Washington, as it is everywhere, they made a thorough test of it by connecting one of their cable wires to an air-line running out 18 miles to the Great Falls of the Potomac, and used the telephone with most excellent results.

Captain F. V. Green, assistant to Major Lydecker, engineer commissioner of the district, was present and made a thorough test, and was entirely satisfied with the working of the circuit.

Mr. McElroy continued: "With the kind indulgence of the Commission, I will read extracts from some letters on the subject of our Washington system. Colonel A. F. Rockwell, in his report to general Newton, after describing the Waring system, says: 'These tests and experiments have been numerous and thorough; they were conducted during a considerable period of time and by a large number of persons. The detailed results, interesting and important, are embodied in the various letters which accompany this report, and to which special attention is invited. Their weight and value will be duly estimated, not only by the scientific attainments, but the practical experience of some of the writers. From their consideration, and from my own observations and frequent participation in the tests and practical working for both telegraph and telephone purposes, I express the opinion that the cable laid by the Standard Underground Cable Company fulfills all the requirements of the service as an efficient and practical substitute for the present overhead system.'"

"In a comparative test made between an air-line and this cable, the underground line was very decidedly the better one, being free from *many*, if not *all*, the disadvantages of the old system."—Spencer F. Baird, secretary Smithsonian Institution, Washington, D. C.

"The theory of this cable is scientifically sound. Its anti-induction feature consists in the use of metallic screens between the wires, a device the effectiveness of which was first pointed out by Prof. Henry. In the test made a remarkable freedom from extraneous noises was observed, the articulation, in consequence, being sharp and clear. The Waring cable, both by its excellent insulation, its protection from induction and the facility of laying, admirably fulfills the requirements of a first-class underground conductor."—George F. Barker, University of Pennsylvania, Philadelphia, Pa.

"Special experiments made by me on this cable indicated that when the leaden covering of the cable was grounded, the induction sounds were decreased in volume by about 98 per cent."—S. P. Langley, director Allegheny Observatory, Allegheny City, Pa.

"The wires of this cable connecting some of the government departments are found to be highly insulated, and the practical tests for telephonic purposes were eminently satisfactory. No perceptible retardation or induction."—W. B. Hazen, brig. and brevet maj.-gen., chief signal officer, U. S. A., Washington, D. C.

"The insulation remains perfect on *all* the conductors in the Waring anti-induction cables laid for my department in the fall of 1883, and the entire system works as well as could be desired for both telegraphic and telephonic service. In fact, I have found your cable better adapted for municipal telegraph and telephone service than any other form of cable I have yet seen, for the reason that it may be looped to and from any given point as successfully as air-lines. I have been in the service constantly since the summer of 1868, and in all this experience have not used any system of wires so thoroughly reliable as I find this cable to be."—Henry R. Miles, general superintendent telegraph and telephone service District of Columbia, Washington, D. C.

"As a medium for telephone communication, this cable is, without doubt, the best in the market. The feature peculiar to this cable is its anti-inductive qualities. Telegraph circuits working in the same cable with telephone lines produce no disturbance whatever on the latter, a result which, so far as I know, is attained in no other underground cable. Air-lines of different lengths were connected to the underground wires, not only without difficulty, but with a marked improvement over the all-air line service."—M. Marean, electrician, Washington, D. C.

"In connection with the telegraph service of the Baltimore and Ohio Telegraph Company during the Chicago convention, we used in transmitting bulletins to the White House, the Capitol, and the various executive departments of the government ten and a half miles of the Waring anti-induction underground cable in connection with our direct air-lines to the convention hall in Chicago, and the working of the air-lines and the cable wires was as nearly perfect as could be desired. I am satisfied that this is the best underground system that I have ever seen or tested, and I believe it is the best cable now offered for any use, meeting as it does all requirements of telegraph and telephone service."—W. H. Clarke, manager Baltimore and Ohio Telegraph Co., Washington, D. C.

"Since the Waring anti-induction cables on Four-and-a-half street were connected up on December 12, 1883, they have been in daily use. No complaint of any kind has ever been made as to the service; no message has ever been delayed; no wires have ever been crossed; there is no 'cross-talk' whatever between the wires in the same cable, and none of the buzzing so common with overhead telephone wires. These cables have been in constant use, without a fault, for telephone, telegraph and fire alarm purposes."—F. V. Green, captain of engineers, U. S. A., Washington, D. C.

"The Waring anti-induction cable in Fairmount Park, connecting the Belmont pumping station and Belmont reservoir, was laid October 4, 1884. It has been frequently measured and tested, and the insulation remains as perfect up to this time as when first laid."—D. R. Walker, chief of the Philadelphia Electrical Department, Philadelphia, Pa.

"In all cases where we have used this cable it has proved entirely satisfactory, coming fully up to the claims which you have made for it, and we believe it will prove the most durable underground conductor that we have yet used. This expression is fully carried out in the large orders which we have placed with you recently. We can cheerfully recommend it to parties wishing such conductors, and especially for places where the durability of other wires might be questioned."—The Union Switch and Signal Co., C. H. Jackson, general manager.

"We have, during the past summer, laid in Pittsburg, for the Bell Telephone Company there, more than 200 miles of wire, and in Chicago, for the Bell Company of that city, nearly as much more."

Mr. Shelbourne: Was the cable laid for these two companies of the bunched style or anti-induction?

Mr. McElroy: That laid in Pittsburg was of both kinds, and in Chicago we used all bunched cable. The Washington cables were all of the Waring anti-induction pattern.

To the Commission: As a result of over four years' work, we have cables working to-day, and working successfully, in Pittsburg, Washington, Philadelphia, New York, Chicago and Milwaukee. We have demonstrated the anti-induction qualities of the Waring cable, and its high insulation, and so far as we have gone, have not encountered any of the predicted electrical bugaboos of underground work. The company is willing to guarantee all work, and its guarantee is as good as a United States bond.

As an evidence of the successful working of the cables of this company down to the present day, Mr. McElroy read a number of telegrams just received from parties now using the cables; among others, one from the Navy Department stating that the Standard underground wires were the only ones which had successfully withstood the test of the previous night's storm. Another from Supt. Miles, of the Fire Department of Washington, said: "The Waring cable has worked well continuously since laid, nearly two years ago." Telegrams from the White House, War Department and Smithsonian Institution were of like tenor. A letter from general manager Jackson, of the Union Switch and Signal Company, said: "Your lead-covered cables are giving universal satisfaction in the railway service of the country."

Benezette Williams, of Chicago, submitted plans of a cellular conduit of concrete. It consisted of a solid block or prism, through which were a number of small ducts for the passage of cables or wires. In laying such a system it was necessary to open the street but once. In reply to a question by secretary Moss, he said that it was practically the same as the Dorsett system, but embraced some improvements.

October 14th J. J. Greenough, referring to his plan previously presented, said that he thought more stress had been placed by electricians upon the effects of induction than the facts warranted. He believed that the simplest and most efficient system would be adopted. Whatever might be the final decision of the Commission, he was satisfied that a large number of people would be disappointed.

J. S. DuBois, representing the Manhattan Electric Cable Co. of New York, submitted the plans of a system which had been purchased from the Continental Cable Company. It is to consist of a subway built of brick or asphalt blocks, through which are to be supported sheet metal pipes, having a longitudinal slot along the top of each. Through this slot, cables are to be supported and at the same time drawn into the tubes by an electric railway motor running upon a track at the bottom of the subway. The whole structure is to be hermetically sealed and kept filled with dry air under pressure, the air compressors being placed in such locations as may be found most desirable. The inventor laid much stress upon the virtue of the compressed dry air as an insulator, supporting its claim by the assertion that if it was possible to run a conductor through a vacuum *the electricity*

Digitized by Google

would leave the wire. The estimated cost of this system is $20,000 per mile.

October 15th being the last day for the reception of proposed plans for the guidance of the Commission in its work of devising a subterranean system, there was a very full attendance of inventors, experts, journalists and financiers, it having been generally understood that the closing session would bring forward several practical plans, and that the proceedings would be of unusual interest.

D. H. Dorsett, of Chicago, presented samples of his conduit as now used in that city, and which is also being put down in Detroit. Maps and plans were also submitted, and the following history of the material and its introduction for electrical work was given by the inventor and owner:

Gentlemen of the Commission:

"In coming before you at this time to present this system, I will first call your attention to the material of which it is composed, giving to some extent a history of it, which dates back to the fall of 1873. I at that time attempted and succeeded in constructing some service work in the way of sidewalks, using a material composed of coal-tar, sand, gravel and other substances, which up to the present time has proved very successful. From that time until the fall of the year 1877 I gave very little attention to it, but since 1877 I have given my entire time and energies to the production of a material which would prove durable for a sewerage construction. The first work of importance I engaged in after I succeeded in securing this material which you see before you, out of which my conduits with some few modifications are largely made, was the construction of a sewer at the Iowa State Penitentiary at Anamosa, where I put in over 6,000 feet of 12-inch pipe. My next work was in Chicago in the following year—1881-'82. In the fall of 1881 I constructed sewers for the Lincoln Park Board of Commissioners. In the spring of 1883, Professor Barrett, city electrician of Chicago, came to my office and asked me if I would like to have my material tested as an insulator. I told him he might do so, and I broke off a piece of sewer-pipe in my office, and he made some tests with it and pronounced it as good an insulator as he had ever found, and from that time recommended it for the work that it is now being largely used for, and a year ago last spring, having succeeded in getting an appropriation for underground work for the city from the authorities of Chicago, he contracted with me to put up for him this material in the shape of a pipe. Those pipes were made nine inches and six inches in diameter, the trunk lines being nine inches, the laterals six. I commenced the construction in the early spring of 1884. In July following he commenced drawing in his wires, which were single kerite wires, drawing ten and twenty of them half a mile at a time—even twenty different wires without abrasion. Those wires have been in operation from 12 to 15 months without any cost for repairs to the city or any disturbance of any kind whatever, so much so, that in the system which I constructed the past year for the Chicago Sectional Electrical Underground Company, Professor Elisha Gray, president, the city has rented a duct all over the south side, and the wires are now in operation in those ducts. While constructing the system for the city, Professor Gray's attention was called to it, and it was at that time I became acquainted with him. He had then invested a large amount of money in trying to find a successful system, and succeeded in finally getting a franchise which would enable him to put in a comprehensive system for the entire city. We have more or less of the ducts filled with all classes of wires. There are fourteen miles of single seven-hole conduits, covering over about ten miles of streets. It is laid—a great deal of it—double, separating the electric light and the telegraph and telephone systems from each other."

Commissioner Hess—"One conduit?"

Mr. Dorsett—"Two conduits separated by about six inches of earth. One is devoted entirely to heavy circuits such as electric light and power; the other to telegraph and telephone circuits. They are, however, united largely in the man-holes, all kinds passing through the same man-holes at the intersection of the streets. In connection with this subject I would like to spread out the maps showing the system that we have there, and also the extent of its construction."

(Mr. Dorsett exhibited two maps.)

"In Chicago we have the areas or sidewalk vaults which belong to the city, the city owning the entire breadth of the street from building line to building line, and under the franchise we have the use of these areas."

Commissioner Hess—"Where are these pipes laid?"

Mr. Dorsett—"Right along the street, having the same relative position in the street as they have on that paper, the sewer coming in the centre. We get outside the water pipes as we are outside the gas. Our pipes are laid on an average about thirty inches deep to the bottom of the trench."

Commissioner Hess—"You don't have them on both sides of the street?"

Mr. Dorsett—"No; the amount of work which has been done in Chicago I can show by this map."

(Mr. Dorsett laid before the Commissioners another map.)

"These white lines show the extent of the system. We have covered the entire south side as far as Harrison street. This portion of the city is covered so that we reach every block with these laterals. On the north side we have simply run a double line up to Lincoln Park, two miles, and on the west side going over the river."

Commissioner Hess—"Have you an aerial system at all?"

Mr. Dorsett—"No; but we have areas that take care of the entire system. In these conduits are the wires of the Chicago Telephone Company, Postal Telegraph, Western Electric Company, Thomson-Houston, the Mather, the Fuller, the Badger, and the Sperry Electric Light companies, the Mercurial Fire Alarm Company, the Gold and Stock Indicator companies, besides the telephone and telegraph wires belonging to the Police and Fire departments. My system consists of one or more multitubular conduits, with man-holes at convenient distances; it is essentially a drawing in and out system. Its chief merit, perhaps, lies in the material of which it is composed. It is a non-metallic material, which underground is indestructible; it is cheap; it is capable of being moulded into any shape, and it has high insulating properties. It is what is known in chemistry as a neutral substance; it is impervious to water or moisture or sewage. It is impervious to illuminating gas, and sewer gas. It is unaffected by the action of acids or alkalies. It cannot rust; it becomes harder with age. Unlike metals, it is incapable of expansion or contraction by heat or frost. It may be classed amongst the asphaltum concretes, but, unlike the street pavements and sidewalks, and other forms of asphaltum concretes, it is unaffected by the elements, and does not deteriorate through exposure or age. It is the one form of this concrete in a thousand that is a success, and this is largely due to the oxide of manganese in its composition, which appears to be the bond between the other elements combined with it, and yet it is a material which, though the ingredients in their proper proportions are given, requires a peculiar method of admixture to make the compound perfect. I would like to ask Professor Gray to talk a little to you now, and after that I will present the system as I have adapted it to the city of New York to the best of my ability."

Prof. Gray—"*Gentlemen of the Commission:* I do not know that it is necessary for me to add very much to what Mr. Dorsett has already stated. He naturally wants me to say a few words inasmuch as I have been the means of putting this system down, as far as it is put down, in the city of Chicago, and naturally in doing that we have had some little experience. As he stated a while ago, I have spent considerable time and considerable money in studying up this question of underground service for electric wires. It is not a question there and I don't suppose it is a question here, between the relative merits of the overground and underground service, inasmuch as the decision there was to go underground anyhow. The next question came up, how best to go underground. There is no system of telegraphic service, either underground or overground or under the sea, that is free from all objections, and perhaps all systems have some advantages. They all have disadvantages—some of them more than others. The best thing we can do is to get a system that, in our judgment will present the fewest difficulties in accomplishing the work. It is not wholly an electrical question; it is largely a mechanical one, and yet the electrical side of the question must not be lost sight of. After studying the problem my conclusion was that I would prefer a large sewer big enough to drive a four horse team through, that we could get in and string our wires around the sides of it; large enough to take care of all the wires—but that was impracticable in Chicago; I don't know whether it is in New York or not. It may be from a pecuniary standpoint, if from no other; but there we would get so far down below the lake—some 10 or 15 feet, because we have to go about 25 feet down to get clear of water pipes, and gas pipes, and all sorts of pipes that are now in the streets, and I assume that that would be the case in any large city. Besides, it would cost millions—a great many millions—to build such a system.

"Throwing that aside as impracticable, so far as we are concerned at least, the question arose, what comes next? I concluded from my experience as a telegraph man, which dates a long way back of this conduit, that it would not be safe to place any wire underground, or in any position out of reach of repairs.

"Modern improvements in manufacturing wires, and insulating wires, and putting wires in position, are very great as compared with what they were even a few years ago; yet it is not safe to conclude that a great system which has cost a great amount of money should be put in any position that cannot be readily and easily gotten at.

"So then, the next question was to devise something or adopt something that would enable us readily not only to put in wires as required, but to take them out, if necessary. That was the first great fundamental feature of the system, and, as Mr. Dorsett has explained, we have in Chicago adopted what we would call the drawing in and out system; that is, we have provided a conduit, or rather a series of conduits, or a conduit with a series of ducts connected with man-holes. I think the average distance in Chicago is 400 feet. We can draw 600 feet very comfortably of any cable that would fill one of these ducts, as we have frequently

Digitized by Google

drawn through one man-hole, two lengths, say 800 feet. It would depend, of course, on the weight of the cable and other things, but we have a system of drawing in and out, machinery for shoving through and catching on to a wire or rope, or whatever we need to handle the cable, with which we shove through at a very rapid rate—perhaps as fast as a horse could trot—hook on to a wire and draw it back, and then hook on to it whatever we wish to draw through; and then by another machine which we employ, when a rope is hitched on to it the cable is drawn through very rapidly, so that I have claimed, and do claim, that the wires as they are now placed in our conduits are as readily gotten at—are as fully accessible as any wires overhead; and they are certainly far more free from any of the difficulties that are constantly happening to overhead wires; because if that wire is once placed in the conduit in a proper cable, properly insulated, it is a very rare thing that it will ever get into trouble. That is our experience from the use of wires now for over two years underground, more or less, in Chicago.

"I do not propose to go into the wire question at all. We have adopted a system like this: We run a conduit system, and let any man who wishes to put in wires, put whatever wires he pleases in there. He may adopt any form of insulation he has a mind to, or no insulation, as one man has done in a single instance, and finds it works very well; but, of course, we do not recommend that. We treat the conduit merely as a receptacle for wires, and we deliver them through streets and into every block. We have laterals running from the main man-holes at the corner of each street, running into the area ways of the various blocks in the city, and from that point the distribution is made for that particular block.

"Now, the question of distribution is one that may be varied, and that is one of the beauties of this system, that it can be adapted to any form of distribution that the circumstances of any particular city may require. Now, we say we have open area ways all around our blocks, and it is a very easy matter when you get into one block to carry a small pipe around under the sidewalks which will be large enough for that block only. No one block can contain a great many wires, so it is an easy matter to provide by a small conduit for distribution.

"Of course we could adopt another method and run a small conduit around every block, and with service wires through area ways. We say that it is not necessary to adopt that, as the other mode is better.

"Another mode is to run into the block and distribute over house tops, if you can make satisfactory arrangements with the owners of the property. Of course there is no objection to that if property owners do not object. In some instances they do that in some blocks in Chicago, for the present, but finally it will come to this distribution system under the area ways, as I think that is the most free from difficulties, and the safest in every respect, and better for the owners of property undoubtedly.

"Our system aims to run down every other street, as you will see. By that means we can touch every block without running in every street, and then an occasional cross conduit cutting all of these through the other way just often enough. It is not necessary to put these through every other street, but every four or five blocks, just often enough to make it convenient to get from one side of the city to the other, and laterally if you want to do it. That is a question that is wholly determined by the need of any particular locality."

"Commissioner Loew—"How large a conduit have you, professor, at any one place?"

Prof. Gray—"We have on La Salle street twenty-six ducts."

Commissioner Loew—"How large is that?"

Prof. Gray—"There we have a ten duct conduit. There is a ten and a nineteen at points like that on Washington street at the tunnel, and La Salle street at the tunnel. Where all the wires must come in to cross the river, we make a larger conduit. We have nineteen holes."

Commissioner Loew—"How many wires are in that? How many will it carry?"

Prof. Gray—"It depends altogether what kind of a wire you are using. One of those ducts can carry four electric light wires, or 125 telephone wires, or 25 telegraph wires. It depends entirely on the thickness of the insulation that the party uses. Mr. Fay, general manager of the Chicago Telephone Company, has some samples which have 125 wires that will go easily in one of those ducts for telephone purposes. I won't say that I recommend that many crowded together, but that is his business, not mine. The Western Electric cable, called the Patterson cable, is made of lead pipe, with paraffine insulation inside. With the size that they make that, the duct will only accommodate four. I am speaking now of electric light wires. So it depends, as I say, upon what you are using wires for, and what the idea is of the man who uses them. I could get one thousand in one duct. You multiply that by the number in any one place and it gives you the capacity. I have no doubt that there are a great many questions that smoe one that is well posted would like to ask on this subject. I probably might overlook points that ought to be brought out, but I would be very glad if any one has any question in his mind that he would ask it."

Commissioner Hess—"What is the strength of that?" (Pointing to section of conduit.)

Mr. Dorsett—"Five thousand five hundred pounds per square inch—crushing strain. The tensile strength averages about 400—about three times that of the best Portland cement concrete."

Prof. Gray—"One of the points in my mind in reference to this material, or anything of the same nature, is the ease with which it could be put in any shape that is desired. Those ducts can be made larger or smaller, as the demands of any particular locality would require. The same principle of operation would form it for one size as well as another, but the object of making the ducts that size was this: You cannot draw in and out wires that are piled on top of each other with any kind of success, if there are a great many of them. Suppose you had a six-inch pipe. Practically, you could not put many more wires in it than you could put in one or two of those ducts and handle them rightly; so that, to use the space economically, it must be divided into ducts about the size you can easily handle in one duct, and that is the object of the subdivision."

Commissioner Hess—"You say you can draw a cable five or six hundred feet through that without injury to the cable, without straining it."

Prof. Gray—"Oh, yes, we have done that. The interior of the duct is very smooth. It is moulded on a polished surface, and, as it is drawn out, it leaves it in practically a polished condition inside."

Mr. R. W. Pope—"You said there were four electric light wires in the duct. Did you mean that was all you could put in, or all that you did put in?"

Prof. Gray—"I mean that in drawing through they put four in a duct—the Western Electric Company. Of course, with a wire made smaller, with thinner insulation than they made, more could be put in."

Commissioner Hess—"What insulation do they use?"

Prof. Gray—"In this particular instance they use what is called the Patterson cable. It is made in a lead pipe. Of course, that lead pipe takes up a good deal of room, and the wire, which is a large wire to begin with, is surrounded by jute; then hot paraffine is injected into this lead pipe until it is filled. All those present who are familiar with electric-light wires understand what the Patterson cable is. There are various kinds of wire, of course, and some with thinner insulation than that, or rather others with no lead pipe, and which, of course, would occupy much less space."

Dr. Moses—"Do those wires go out at the man-holes?"

Prof. Gray—"Yes. At the corner of every street there is a man-hole, and from that man-hole there is what we call a lateral (indicating on the map). These conduits come along here. They all run into that same man-hole."

Dr. Moses—"How do you make your local distribution?"

Prof. Gray—"We leave that question to the wire-users. We deliver them in the block, and charge them so much for the space, or so much for the wire and the distance, and they arrange with the property owners. However, the matter now, as we have arranged to do it, is to control not only that, but to deliver the wires to every building by a small duct, which will run right around the block, so arranged that you can take out wires in any building."

Mr. McDonough—"What arrangement is there for drawing a lead armored cable through the duct, taking the spring out of it if it is rolled from the drum?"

Prof. Gray—"The cable is delivered on a drum. It stands up over the man-hole. Then there is a guide to start the thing. A man stands there and feeds it down and keeps it to the right curve. There is a capstan arrangement situated in the other man-hole opposite the duct, which may be the whole length of two blocks. If the cable is not too heavy we can draw two blocks very comfortably right through one man-hole."

Mr. McDonough—"Is that sufficient to make the cable perfectly true, and have it go in on the line without any spring at all?"

Prof. Gray—"A lead pipe, you know, has no spring on it. It stays where it is put. Of course as it goes in it is straightened. We experience no trouble whatever in practical work. We have put in certainly twenty miles of cable."

Mr. Dorsett—"Would not that be one of the advantages of a small duct?"

Prof. Gray—"Of course you could have the cable so large that it would not be manageable. Any cable that will go in that duct, very readily takes its shape as it goes in."

Mr. McDonough—"The contention I made was that coming into contact with the surface of this hole in the duct you would get up so much friction there that you would not be able to draw it through from man-hole to man-hole?"

Prof. Gray—"The only answer I have to make to that is that we do it. This reminds me of the fellow in jail to whom his lawyer came and said, 'My dear fellow they can't put you in jail.' 'But,' said the man, 'I *am* in jail.'"

Dr. Moses—"When you wish to make a distribution for one particular block do you use a special cable for that block?"

Prof. Gray—"We use whatever wire is needed at that time."

Digitized by Google

Dr. Moses—"Do you use the cable specially provided from a central station running from the main?"

Prof. Gray—"We take a wire out from the main at any point we want. Some people put in the single wires, you know. They can draw a bunch of wires through that duct, whatever it will hold, or a single wire, and in that case of course they have nothing to do but just divert that wire into any one of these blocks."

Dr. Moses—"Do you provide for the wants of each block as you reach it?"

Prof. Gray—"We provide the space. We do not provide the wires. We provide the conduit."

Dr. Moses—"I simply wish to know what the facilities may be for supply?"

Mr. F. L. Pope—"Do you have any instance where a small pipe runs from the man-hole to the corner of the block, and different classes of wire are put into the same conduit, electric light and telephone wires for instance, or do you provide two separate channels from the man-hole to the block?"

Prof. Gray—"In some instances there are two separate channels, but in many instances there is only the single 7-hole conduit. That we do wherever it is desirable for any reason whatever to lay two sets of laterals. Otherwise we do not. We have that in some cases; in others we have not. We have conduits all over the city; most of them that size, and we keep all of the electric light wires in one, so far. That was the design to keep the electric light and heavy current wires of all sorts in that set of conduits."

Dr. Moses—"How far apart are they?"

Prof. Gray—"About six inches of earth between the two conduits."

Mr. Dorsett—"It would average about six inches."

Mr. F. L. Pope—"What are the usual methods adopted for making the jointings of the wires in the man-holes?"

Prof. Gray—"Well, in the Patterson cable, which is more used, perhaps, there than any other, whenever they take a wire out they have a mode of sealing the jointing up, and then it doesn't need any protection farther than the ordinary insulation."

Mr. F. L. Pope—"The joint is simply made in the wire, and then the insulating covering is replaced over it in some way?"

Prof. Gray—"Yes."

Dr. Moses—"Is there any delay when a service is asked for in a householder getting it?"

Prof. Gray—"There is no delay on our part. We have four or five electric light companies in our conduits. Now, if a man wants a light it is the company's business to get a light to him, not ours. We charge for the use of the conduit. Then there is a ticker service. We rent them the space in the conduit and they get the wires to their customers. That is a part of the business we pay no attention to. Of course, if it were our business we would see that it was done, but we cannot be a conduit company, and a ticker company, and an electric light company, and a telegraph company, and everything all at once; it is not practicable. The services must be divided up; and that divides it up very nicely."

Dr. Moses—"When you lease your conduits do you do it according to the diameters of the insulation or the diameters of the wires?"

Prof. Gray—"Where we wholesale it we go by the space. Now to answer the question that you will ask me next—we own a certain number of wires for individuals. For instance you have a private wire. You want a single wire. You do not want to rent a whole duct. We take our chances on that and buy a cable and put it in ourselves. We rent you a wire and put it in your office, and wherever you want it from our own cable. We now have one cable in most of that south side system; most of the cases are covered by the various companies, the electric light, the telephone, the telegraph, the district telegraph and the ticker service, and all that are represented by companies, and it is their business to look after their own customers."

Commissioner Hess—"Do you guarantee the effective working of the wire?"

Prof. Gray—"Not at all, only so far as it is affected by the conduit."

"Commissioner Hess—"I mean so far as it is affected by the conduit."

Prof. Gray—"We keep the conduit in order. If the conduit gets broken, or anything of that kind, it is our business to repair it."

Commissioner Hess—"Have you had any complaints as to the unsuccessful working of the conduit?"

Prof. Gray—"We have not."

Commissioner Hess—"How long have you been working it?"

Prof. Gray—"We began laying this system last fall. We have had wires underground there for the past two years. How long ago was it? (To Mr. Dorsett.)

Mr. Dorsett—"A year ago last spring."

Prof. Gray—"These wires have been working since that time. They have now adopted our conduit for the balance of the city. We began renting space as soon as we got the conduits down."

Mr. R. W. Pope—"Practically, professor, how about the joints in these man-holes? Do many of the cables run through, or are they joined up at the man-hole?"

Prof. Gray—"That depends upon the weight of the cable. They aim to draw as long a section as they can, and not injure the cable, so as to have as few joints to make as possible. That is a mere matter of economy with them. With the Patterson cable, for instance, they draw through two blocks without making a joint, but, if necessary, a joint is made in each man-hole. That is a practical question which comes up to the cable men and not to us."

Mr. R. W. Pope—"I wanted to know what the experience was, that was all."

Prof. Gray—"That is about it; in a great many instances they make a joint about every other man-hole, which means every other block."

Dr. Moses—"Have you a system of separate service in each one of these blocks?"

Prof. Gray—"No."

Dr. Moses—"Have you had experience as to running electric light circuits with telephone circuits?"

Prof. Gray—"I know the result of telephone and telegraph service when run near together. Of course, we all know that telephones are more easily affected than any other class of service. There is no difficulty in working electric light and telegraph wires together. There is no difficulty in working electric light wires and telegraph wires in the same conduit, if you will let me put the wires in and fix them as I want them. But as a precaution which any one would naturally take, we prefer to have all the heavy current wires in a duct by themselves."

Commissioner Hess—"You claim you can run an electric light and a telegraph wire in the same duct?"

Prof. Gray—"Oh, yes."

Commissioner Hess—"Without injury to the electric light, I suppose?"

Prof. Gray—"Without any injury to either."

Mr. R. W. Pope—"Are there any wires using the Gray Harmonic system through the conduit?"

Prof. Gray—"Yes; the Harmonic system runs through the Postal cables, and I have worked telephones right inside of that. Of course, if they were exposed, and had no shields of any kind, practically you could not use your telephone at any great distance."

Dr. Moses—"Are the shields grounded?"

Prof. Gray—"Oh, yes, they lie right on the conduit, and as that conduit is iron, they must be grounded very effectually."

Mr. Moore—"In case there should be an explosion of a steam pipe or anything near the conduit, would that cause any trouble?"

Prof. Gray—"It is readily mended. It is the easiest kind of a system to mend in case of an accident."

Mr. Moore—"In doing so, you would have to take out the cable?"

Prof. Gray—"Not necessarily. You can make that in sections, and take one of those sections right out and put it together without disturbing the cables that are in there. It might be advisable, in some cases, if you did not have it full—it might be easier to draw the cable out and draw it in again than it would be to put that conduit in in sections and join it up, but that is a question that I would settle at the time when the accident happened."

A Gentleman—"In Chicago you have area ways in which you lay your pipes. Now, I would like to know how you lay them in New York. Take it down in Wall street, take it in all the lower part of the city of New York—there are no areas there."

Prof. Gray—"Your distribution would either have to be from the distributing pipe in the street, around the block or over the housetops, from the distributing point there."

Commissioner Hess—"Or a court yard."

Prof. Gray—"Or court yards. It is not limited to any one variety of distribution at all. It is a question that has to be settled in every city according to the circumstances you have to meet."

A Gentleman—"Take it where they would have to branch off parallel, 45 degrees or around a corner across the street, how would you get there? In Chicago you have square corners, but New York doesn't have square corners."

Prof. Gray—"Your question is, Can you lay a conduit on a curved street? Why, there is a certain amount of curve that can be put into these pipes, if the curve is not too sharp, but I take it there is no street but that you can meet the objection in this way—you can lay your conduits as far as you can go straight or on a curve, and put a man-hole in there, and go off in the other direction."

A Gentleman—"How would you draw in your cable on a curve?"

Prof. Gray—"We would draw it in. Of course there is more friction on a curve than on a straight hole, though if the curve is down there is not. You could draw a cable that sagged down more easily with a curve than you could with a straight hole. If you were suspending a cable in mid-air it would have a curve."

A Gentleman—"Wouldn't you have trouble with moisture in such a trap as that?"

Digitized by Google

Prof. Gray—"I would not have that trap in it. I merely spoke of that for illustration. It would be better to drain toward the man-holes from the centre."

Mr. F. L. Pope—"Your idea is that wherever the curve is too great to draw the cables conveniently, you put in an angle and a man-hole?"

Prof. Gray—"Yes, an angle and a man-hole."

Mr. F. L. Pope—"You have been to Boston, I suppose?"

Prof. Gray—"Well, I have. You can generally avoid a curve there by going through a narrow alley."

Mr. Geo. Worthington—"With the conduits, Professor, that you have described, has there been any trouble caused by sewer gas?"

Prof. Gray—"Not the slightest. The conduits are impervious to sewer gas."

Mr. Dorsett—"I would like to show my plan as I have adapted it for New York. The object of the Dorsett system is to facilitate the laying and distribution of the conductors throughout a city, or any part of the same, to the better insulation of said conductors, and the prevention of inductive or other injurious effects, arising from the close proximity of circuits for different purposes, such as telegraphing or telephoning on the one hand, and electric lighting on the other.

"The system is comprehensive and complete, in so far as it provides for the economical laying and working of all the circuits which the present needs of business and communication require; in other words, it provides for the running in close proximity of circuits for carrying the strongest and most intense currents, as well as those for carrying the most feeble electrical impulses such as are produced in the operations of telephony, and this in such manner that there will be no danger to any circuit from such proximity, while all are brought within ready and easy access.

"The system comprises main and branch pipes, or conduits, in which the conductors are carried in the manner hereinafter specified. The main consists of three separate and independent pipe lines: one containing such wires as are required for communication with distant points, or other cities, and which are designated as trunk lines; another pipe contains the wires of circuits used in local communication, and inter-communications, such as telephone lines, fire and burglar-alarm circuits, and the like; while the third contains the circuits used for electric lighting, transmission of power, or those industrial and domestic applications of electricity which require powerful currents.

"The lines are run through the streets of a city, at such a distance below the surface as will insure protection against bending or injuries from repair of the streets, subsidence of the surface soil, and the like. Generally, and whenever convenient, the lines are run midway between the buildings on either side of the way, and with the trunk line between the other two.

"At the intersection of the streets the three lines are run into what are termed man-holes—that is, subterranean chambers large enough to permit a man to enter them for obtaining access to the pipes, or conductors therein. These man-holes are constructed in a way to keep out water, moisture, moist air, sewage, illuminating and sewer gases, and other matter, and are provided with suitable detachable double covers. The pipes pass through their sides, and the wires can be carried from one pipe to another, as may be required.

"Between the man-holes, and along the blocks, or squares, are numerous subterranean chambers, which are called, or designated, as hand-holes. These are placed as nearly as practicable opposite the dividing lines, between the buildings, so that in places where the buildings are of about the same frontage two hand-holes are required for each group of four houses, as will shortly be explained.

"The hand-holes are for the purpose of running branches from the two pipe lines, on either side of the trunk line, which latter does not pass through them. They are much smaller than the man-holes, though constructed on the same principle. The pipes containing the signaling, and those with the electric light wires, enter these boxes, and one or more of the wires or branches from the same are brought up to a higher level, and taken off into smaller branch pipes to the buildings. Four of the smaller pipes run from each hand-hole, one to each of the four nearest buildings, and in laying the hand-holes and branches it is desirable to locate the former as near as possible to each other in order that all the branches may be placed in laying in one small trench. Of the two branch pipes that run to each house, therefore, one contains the wires of an electric-light circuit, the other those of a telephone or other signaling circuit. In the case of the former there may be one or more leading and return wires for the same house circuit, or the leading wire or wires to one house, and the return wire or wires from another. This is obviously a matter of choice, and not essential to the main features, that of isolating the electric light circuit from the others.

"The material is an insulating compound, containing coal tar, paraffine, silicious sand, pulverized ashes and cinders, oxide of manganese, and ammonium chloride, in certain proportions.

"This material I use for the mains of my system, preferring it to all others. The joints between the sections of the pipes may be either of metal, or the entire conduit may be made from the insulating material alone. I make the man-holes of this material also. The hand-holes are also made of this material.

Inasmuch as the mains are buried deep, and are of comparatively large size, they are advantageously made of the insulating compound alone, but it is extremely undesirable to bury the branch pipes deep, in fact they should be but little below the surface or flagging of the street, and as they carry, usually, only one or two wires, they should be made quite small. Instead of making them, therefore, of the compound alone, I use iron pipes which are filled with the compound, through which passages are formed for the wires. By this means the requisite strength and insulation are obtained.

That section is exactly a duplicate of what we make. The sections are made in my factory at the rate of 1,000 to 1,200 feet a day. They are loaded on the cars as fast as made and shipped to Detroit where I am laying about a mile a week. There are no leaks. I take some of this liquid asphaltum and use it for making the joints. Professor Gray said he did not want the ducts made perfectly continuous: he would sooner have the dry air there.

A Gentleman—"How many wires do you carry through a section of that kind?"

Mr. Dorsett—"It depends on the insulation a good deal."

Mr. Shelbourne—"Is that the patent of August 2d, 1881?"

Mr. Dorsett—"The patent of August 2d, 1881, is the patent on my original material. There is a subsequent patent."

Mr. R. W. Pope—"These pipes are put down in this plan alongside of each other. Can they be put one above the other?"

Mr. Dorsett—"It depends upon the pipes in the streets."

A Gentleman—"Can you give an estimate of what the cost would be of laying it in New York?"

Mr. Dorsett—"I have not made any estimate in regard to that."

George C. Richardson, of Philadelphia, submitted samples of a conduit, containing five ducts, which he proposed to make of sand and cement. After moulding, the sections were submitted to the cold fumes of charcoal, which restored to the cement the element taken out in its manufacture, and left the pipe as hard as the original rock. He proposed a separate pipe for each company with accommodations for as many wires as might be required. He claimed that the joint by which the sections were united was of special merit. One end is concave, and its opposite convex, an annular ring and a corresponding projection giving the joint unusual strength, the whole being covered with a sleeve and securely cemented. The vaults on each block are to be double walled in order to provide an air space around them.

J. J. C. Smith, of the Okonite company, who had previously presented samples of cable, and a sample joint-box, submitted a plan of the city showing the method by which his armored cables were to be laid down in order to accommodate every block. He was followed by Charles A. Cheever, president of the company, who pointed out the economy of the system, as well as the simple manner in which the cables can be laid down, the trench being dug, the reeled cable run over it, and the pavement immediately restored.

Judge Koch, president of the Dock Commission, representing the Wheaton Sub-Electric Company, exhibited a model of an iron conduit, which it is proposed to make 15 inches in width and from 3 to 9 inches in height. Glass blocks about an inch in thickness, with suitable grooves upon the surfaces to admit the wires, are piled one above another after the wires are led through them. These wires were bare as shown in the model, but the inventor stated that if difficulty arose from the condensation of moisture on the glass supports, the wires might be insulated.

John Grieves presented samples of a plan for inclosing individual wires in prepared asbestos paper, embedded in an insulating compound which he stated had been approved by W. H. Preece, of the British government telegraph system.

Dr. Gough, representing the Cogswell Manufacturing Co., showed a sample of Mrs. Cogswell's method of insulation, in which bare wires are cemented between grooved glass plates, which may be packed together and placed in a trench, where it is supposed they will remain forever.

Mr. Johnston, of Philadelphia, representing the American Sectional Underground Conduit Co., of that city, had prepared an extended paper, both argumentative and descriptive, but owing to the pressure of business he was requested by the Commission to confine himself to the conduit proper. He stated that it had been in operation in Philadelphia for three years. That he had brought no samples, for the reason that being in practical use so near New York he hoped that the Commission would personally inspect it. In 1883 they had 249 lights in operation, and the overhead companies had given them but three months to live, but they were still in existence and had 290 arc lamps operated from the conduit. It might be asked why more had not been done, but the system had been offered to telegraph and telephone companies who had declined patronizing them.

The plans and specifications of Thomas G. Turner, were the last which were presented to the board. Mr. Turner has considered the problem as primarily one of civil engineering. He proposes a double route, a main conduit up each side of the city

Digitized by Google

(connected across town in the vicinity of Bowling Green and other stated points), which will require laterals of about half a mile in length, the average distance of all instruments being about one-quarter of a mile from the tunnel. Its construction to be similar to that of an ordinary brick sewer(the work to be done by tunnelling), and located below the water pipes, which according to engineering authority is the only available space in most of the streets of New York. The interior dimensions suggested are four feet in height by six in width. The distributing laterals are to be laid just below the pavements, and consist of a core made of terra cotta or similar material with suitable grooves along the sides and top for the reception of cables and wires, which are preferably lead covered for mechanical protection as well as the neutralization of induction. The cables being placed in the grooves, the whole structure is encased in heavy sheet lead. For convenience in gaining access to any wire of a cable at any point, the inventor has devised a cable of such construction that any wire may be selected and led out by opening the covering for a space not exceeding one foot in length. The largest sample distributing case as shown is 5x8 inches in dimensions, having a capacity for 12 cables, and conductors for 400 incandescent lamps and 200 arc lamps. It may be increased in size and changed as to arrangement as the main conduit is approached, and it is obvious that the lead covering may be cut into and connections readily made at any point. The trunk lines are led through the main conduits, in lead cables placed on metal supports, and wherever necessary, branches are taken out at man-holes located at the junctions of the cross streets. The plans presented by Mr. Turner bore evidence of very thorough examination of the territory which it is proposed to provide with electrical sub-ways. He claims that it would be permanent beyond question, and provide for all known service in a practical and thorough manner; and he further claims that as a comprehensive system the cost of plant and maintenance will be lower than any plan offered for the consideration of the board, and that the interruption to the traffic of the city will be avoided by doing the work as proposed, and that three-quarters of all the conductors can be run via the tunnels and therefore are not subjected to the conditions which mainly make underground electrical communication an unsolved problem.

There being no other business before the Commission, the session closed at five o'clock, and such plans only as have been formally presented will be considered by the Commissioners hereafter in executive session. They will visit Philadelphia and possibly Chicago before arriving at a decision upon what system they will recommend for adoption.

ANNUAL REPORT OF THE WESTERN UNION TELEGRAPH COMPANY.

FOR THE YEAR ENDED JUNE 30, 1885.

CAPITAL STOCK.

The capital stock of the company is $80,000,000, of which $20,969 belongs to and is in the treasury of the company. A small portion of the capital stock is still represented by certificates of indebtedness in the hands of the Union Trust Company, in trust for the parties entitled thereto.

BONDED DEBT.

The bonded debt at the close of the year was as follows:

Bonds due March 1, 1900, 6 per cent	$911,250 00
Bonds due May 1, 1900, 7 per cent	4,920,000 00
Bonds due May 1, 1902, 7 per cent	1,373,000 00
	$7,204,250 00
Less balance of sinking funds appropriations not yet used for redemption of bonds held by the Union Trust Company trustees	329,364 34
	$6,874,885.66

During the year, sterling bonds due March 1, 1900, to the amount of £2,100, were redeemed by the trustees of the sinking fund.

BUSINESS OF THE YEAR.

Surplus, July 1, 1884		$4,157,468 89

The revenues, expenses and profits of the year ended June 30, 1885, were as follows:

Revenues	$17,706,833 71	
Expenses	12,005,909 58	
Profits		5,700,924 13

From which there was applied:

For dividends	$4,999,325 41	$9,858,393 02
For interest on bonds	495,072 50	
For sinking funds appropriations	39,991 00	
		$5,534,388 91
Deducting which, leaves surplus, June 30, 1885, of		$4,324,004 11

Represented as follows:

Surplus of net revenue for the year over dividends, interest and sinking funds appropriations	$166,535 22
Surplus at commencement of the year as above	4,157,468 89
	$4,324,004 11

The expenses for the year were:

For operating and general expenses	$8,544,553 79
For rentals of leased lines	1,822,542 58
For maintenance and reconstruction	1,146,871 49
For taxes	301,731 75
For equipment of offices and wires	190,209 97
Total expenses, as above	$12,005.909 58

The above classification of expenses shows that all disbursements for *reconstruction* and repairs, and all payments for leased lines, taxes, and cost of equipments, including the equipment of new offices, have been charged as usual to current expenses before profits are ascertained. Nothing is charged to construction and paid for out of profits but new and additional lines and wires, and buildings, and stocks purchased in leased lines. The cost of a considerable amount of new property such as the equipment of additional wires and new and additional offices with instruments, batteries and fixtures, is every year charged to and paid for as current expenses.

The falling off in gross revenues is due almost entirely to great reductions of rates for the transmission of messages; for the volume of the traffic was greater than that of the previous year. The increase of over twenty thousand messages (exhibited in the table of statistics) shows a very small portion of the actual increase of traffic; as the increased number of leased wires, over which the lessees handle their own messages, takes a very large number of messages out of the count.

The receipts for, and the expenses of, handling domestic messages show that the average rate collected, per message, during the year, was only 32$\frac{1}{10}$ cents per message, against 36$\frac{1}{2}$ cents during the previous year, and 38 cents in the year previous to that; whilst the average cost to the company has been 24$\frac{8}{10}$ cents per message, against 25$\frac{2}{10}$ in the previous year, making an average reduction of 4$\frac{4}{10}$ cents per message, and a difference in the profits of 4$\frac{2}{10}$ cents per message, which, on the volume of business handled, is equal to nearly two and one quarter per cent. on the capital stock.

The loss of 4$\frac{4}{10}$ cents per message as compared with the previous year makes a difference in the gross revenues of $1,852,249,65. Had the reduction been an average of not more than two cents per message, the net results would have been better than the previous year.

The leasing of wires by the company instead of handling the business itself has not proved a profitable change. It has only been done to a limited extent—less than five per cent. of the gross earnings—but sufficient to demonstrate that there is little profit in leasing wires at prevailing rates after paying for their equipment and maintenance.

There has been a falling off in revenues from the gold and stock department on account of the great reduction in the rates for quotation instruments; but there has been an increase in the revenues from leased wires, and from rentals of offices in the company's buildings. The revenues from the company's large investments in telephone and other companies have been well maintained.

GENERAL STATEMENT.

The following exhibit shows the revenues and disbursements of the company for nineteen years from July 1st, 1866:

Surplus of income account, July 1, 1866	$ 275,357 24	
Net revenues for nineteen years, from July 1, 1866, to June 30, 1885	78,080,661 11	
Making an aggregate, June 30, 1885, of		$78,356,018 35

During this period there was applied:

For cash dividends to stockholders (including dividend payable July 15, 1885	44,130,029 58	
For cost of 59,606¼ shares of Western Union Telegraph stock, purchased and owned by the company, which was distributed to stockholders in 1879	3,302,198 90	
For cost of 72,010 shares of Atlantic and Pacific Telegraph stock, purchased and owned by the company, the proceeds of which in Western Union stock were distributed to stockholders in 1881	1,806,250 00	
For interest paid on company's bonds	7,695,803 09	
For cost of 396 44-100 shares of Western Union stock, purchased and owned by company, which were canceled to make the capital stock, after the issue of the new stock in 1881, exactly $80,000,000	26,836 00	
For amount reserved for interest on bonds and for sinking funds, accrued to June 30th, but then not yet due and payable	106,086 64	
		$57,067,204 21
Leaving a surplus of		$21,288,814 14

Which is represented as follows:

Construction of new lines, erection of additional wires, patents, etc	$9,896,160 08
Purchase of telegraph lines, and of the stocks of companies leased by the Western Union Company, upon which interest or dividends are paid as rental	2,448,182 66
Goldand Stock Telegraph Co.'s stock (18,905 shares)	1,176,009 00
International Ocean Telegraph Co.'s stock (15,170 shares)	961,606 24

Digitized by Google

Brooks' Underground Telegraph Co.'s stock (1,000 shares)		95,000 00	
Southern Bell Telephone and Telegraph Co.'s stock (1,687 shares)		84,325 00	
Sundry other stocks and bonds		93,739 68	
Western Union bonds, redeemed and canceled		1,389,883 27	
Sinking Funds (portion not yet used for redemption of bonds, exclusive of interest allowed by trustees)		290,567 82	
Broadway and Dey street building	$2,365,639 52		
Less: Amount provided from the proceeds of the bonds	1,802,202 00		
		563,437 52	
Real estate, other than above		283,608 50	
Supplies and material on hand unissued		182,290 08	
Surplus, June 30, 1885		4,324,004 11	
			$21,288,814 14
On account of these assets, a stock distribution was declared in 1881, to the amount of			15,526,590 00
Deducting which, leaves a balance of			$5,762,224 14

Of the $44,130,029.58 paid to stockholders in cash dividends during the last nineteen years, as shown in the foregoing general statement, $22,996,102.24 have been paid in dividends since the consolidation of January, 1881; and in addition thereto, $5,369,-945.11 have been advanced and paid within same period for new and additional properties—making an aggregate of $28,366,047.35 paid out of the net revenues of the company since the date of its present capitalization, and within four and a half years.

From January 1, 1881, to June 30, 1885, $6,369,945.11 were expended for construction and purchase of new lines, and for telegraph and telephone stocks, real estate, and other new property. Of this, $1,229,915.22 (expended between January 1st and September 30, 1881), were appropriated out of the profits prior to October 1, 1881—$1,000,000, were provided for by that amount of bonds sold, and $4,324,004.11 have been advanced (since October 1, 1881) from the surplus June 30, 1885.

The surplus of $4,324,004.11 is that shown in the quarterly statement for June 30th, and represents only the accumulated surplus since October 1, 1881, when appropriations out of earnings for construction and new property were suspended. The moneys necessary to meet these outlays have, nevertheless, continued to be advanced from the treasury as a construction loan to that amount, reserving the right to replace such advances from the sale of assets. The whole accumulated surplus since the capitalization of previous surplus by the issue and distribution of capital stock in January of 1881, is $5,762,224.14, balance as shown in the foregoing general statement. Of this surplus $5,369,945.11 has been invested in new and additional properties, in addition to the $1,000,000 derived from the sale of bonds.

The accumulated balance of $5,762,224.14, shown in the above statement, of which $5,369,945.11 has gone into the plant, is of precisely the same character as the accumulation and investment in new properties of $15,526,590.00 prior to 1881, which, after the most exhaustive investigations in the courts, was finally decided by the Court of appeals of the State of New York to have been legally and properly capitalized by the issue and distribution of capital stock to an equal amount therefor.

STATISTICS.

The following Table exhibits the mileage of lines operated, number of offices, number of messages sent, receipts, expenses and profits, for each year since 1866.

YEAR.	Miles of Poles & Cables.	Miles of Wire.	Offices.	Messages	Receipts.	Expenses.	Profits.
					$	$	$
1866	37,380	75,686	2,250	....			
1867	46,270	85,291	2,565	5,879,282	6,568,925 36	3,944,005 63	2,624,919 73
1868	50,183	97,594	3,219	6,404,595	7,004,560 19	4,362,849 82	2,641,710 87
1869	52,099	104,584	3,607	7,934,933	7,316,918 80	4,568,116 85	2,748,801 45
1870	54,109	112,191	3,972	9,157,646	7,138,737 96	4,910,772 42	2,227,965 54
1871	56,032	121,151	4,606	10,646,077	7,637,448 85	5,104,787 19	2,532,661 66
1872	62,033	137,190	5,237	12,444,499	8,457,095 77	5,666,863 16	2,790,282 61
1873	65,757	154,472	5,740	14,456,832	9,333,018 51	6,575,055 82	2,757,962 69
1874	71,585	175,735	6,188	16,329,256	9,262,653 98	6,755,733 83	2,506,920 15
1875	72,833	179,496	6,565	17,153,710	9,564,574 60	6,335,414 77	3,229,157 83
1876	73,532	183,832	7,072	18,729,567	10,034,983 66	6,635,473 69	3,399,509 97
1877	76,955	194,323	7,500	21,158,941	9,812,352 61	6,672,224 94	3,140,127 67
1878	81,002	206,202	8,014	23,918,894	9,861,355 23	6,309,812 53	3,551,542 70
1879	82,987	211,566	8,534	25,070,106	10,960,640 46	6,160,200 37	4,800,440 09
1880	85,645	233,534	9,077	29,215,509	12,782,894 53	6,948,956 74	5,833,937 79
1881	110,340	327,171	10,737	32,500,000	14,393,543 85	8,485,264 13	5,908,279 72
1882	131,060	374,368	12,068	38,842,247	17,114,165 92	9,996,095 92	7,118,070 00
1883	144,294	432,726	12,917	41,181,177	19,454,902 98	11,794,553 40	7,660,349 58
1884	145,037	450,571	13,761	42,076,226	19,632,939 60	13,022,503 90	6,610,435 70
1885	147,500	462,283	14,184	42,096,583	17,706,833 71	12,005,909 58	5,700,924 13

Attention is called to the preceding table which shows the steady and continued growth of the company. During the year nearly 2,500 miles of pole lines; and nearly 12,000 miles of wire have been added to the plant, and the number of offices has increased to over 14,000, with nearly 23,000 employés. The magnitude of the company's system may be better comprehended when you realize that its pole lines and cables would extend around the globe nearly six times, and the length of its wires would girdle the earth eighteen and one half times.

On account of the general stagnation of trade the year has been a hard one on almost every class of business and every department of industry. Had there been any life and activity in commercial traffic, the lower rates would doubtless have brought us an increase of business more nearly compensating in revenue for the loss by the reduction of tolls. Since the close of the fiscal year on June 30th there has been some promise of a revival of trade which it is believed will bring us largely increased business.

The outlay for construction and new properties during the year amounts to $676,449.88, which is less than has been required in any year for a number of years past. With the extensions of railroads and growing demand for additional wires, this requirement is not likely to be materially reduced. We have thus far been able to meet this outlay from our surplus revenues without interfering with regular quarterly dividends.

The assets in the treasury have been increased by the addition of $40,000, in bonds of the Chicago and North Western Telegraph Company, and $100,000 in the bonds of the Southern Telegraph Company, purchased during the year.

Without a single defalcation, or delay of a single day, this company has during its entire history met the interest on its bonds and those of its auxiliary companies, and paid all rentals of leased lines, whether in form of interest on bonds or dividends on stocks, and whether especially guaranteed or unguaranteed. For a period of eleven and one-half years it has paid regular quarterly dividends, with but a single exception, which was compensated for by an extra dividend within six months thereafter.

Respectfully submitted,

NORVIN GREEN, President.

SUBMARINE BLASTING AT FLOOD ROCK.

Nine years of patient toil under the skilled direction of General Newton and Lieutenant Derby, culminated on October 11th in the breaking up of Flood Rock, which has formed one of the principal obstructions to navigation through the channel at Hell Gate. Although surpassing in magnitude any previous achievement in that branch of engineering, the explosion of 140 tons of dynamite, had been so carefully planned that no unusual results followed the firing of the mine beyond the limits to which its destructive effects were confined.

Electricity was the indispensable agent through which success was attained, yet experience had taught that its use might be somewhat restricted, therefore concussion was depended upon to ignite a large proportion of the cartridges. The advance made in the economical use of battery may be appreciated by comparison with the previous blast at Hallett's Point on September 24th 1876, when 960 cells of battery were used to ignite 25 tons, while on this occasion but 60 cells were required for six times that amount of dynamite.

Preparations had been made at various points within a range of 300 miles to observe the effect of the explosion, but owing to a delay of about 15 minutes in the firing, the indications were not so generally noticed as they otherwise might have been. Two empty carboys which were left on the island, were subsequently found unbroken, showing that it might have been possible for an observer to have remained unharmed upon the little tract of nine acres, which almost entirely disappeared from view. The electrical material used was prepared under the direction of Colonel M. W. Goodyear of E. S. Greeley & Co., and the devices for the explosion were planned by General Abbott, who has given great attention to this branch of electricity. There are so many details to be carefully looked after in an operation of this magnitude, that all who participated are fairly entitled to congratulations upon its unqualified success.

The great advance in the development of instantaneous photography, should also be noticed, as well as the enterprise of the daily press, by which very accurate pictures of the upheaval of the waters, were placed before the thousands of readers of the New York journals on the following morning.

HEWITT AND CLARKE'S TELEMETER SYSTEM.

The enterprise of Mr. Cyrus W. Field and his hearty appreciation of the various uses of electricity, was thoroughly manifested in the fitting up of the Washington building at No. 1 Broadway. The adoption of the telemeter system in its various branches, in order to complete the equipment of such a structure, was determined upon by Mr. Field when his attention had been called to the subject. The telemanometer is perhaps the most interesting and useful part of the apparatus. By its use, the steam pressure may not only be learned at any distance from the boiler-room to which the wires are led, but a complete record of its fluctuations are preserved for future reference. The dial of the steam gauge may be practically duplicated at any distance, and it is obvious that a similar result may be obtained in connection with gauges or dials of any description. At Holyoke, Mass., the height of water in the reservoir of the Holyoke Water Power Co. is similarly recorded in the office, while at the Meteorological station in Central Park, Prof. Draper has for a year past used the telethermometer for indicating and recording

Digitized by Google

changes in temperature. A similar application of these instruments is also to be made in the government Bureau of Engraving and Printing at Washington, where they will be required to record the temperature in the various drying-rooms connected with the printing of notes, bonds, stamps, etc.

The perfection to which this system has been brought is such that its future adoption in connection with various industries is merely a question of its becoming generally known. There is little doubt that wherever the consumption of fuel for heat or power is a considerable item of expense such devices soon pay for themselves, besides furnishing valuable data for improvements in the service with which they are connected.

PETITIONING TO VACATE THE BELL TELEPHONE PATENT.

A Washington press despatch says that several petitions have been presented to the Department of Justice asking that suits in equity be brought to vacate the Bell patents now owned by the American Bell Telephone Company. Two of these petitions were presented by the Globe Telephone Company, and the other by the Washington Telephone Company. The Department of Justice has referred the petitions, with the accompanying papers to the Department of the Interior, for the "report, advice, and recommendation of the Secretary of the Interior." The Secretary of the Interior, in turn, has referred each to the Commissioner of Patents for his "report and opinion."

Mr. Montgomery has not yet reported to the Secretary of the Interior, but has submitted to him a brief summary of each case. Secretary Lamar directs and will order that, inasmuch as his "advice, opinion, and recommendation" are invited, he will ask all the interested parties to appear before him and the Commissioner of Patents, exhibit all facts, and answer the following questions :

First, Has the government the right to institute and maintain such a suit for such a purpose? and, second, if it has, do the facts as they shall be presented warrant or demand that such suit be brought? All proceedings will be had publicly.

STORAGE BATTERIES FOR TEMPORARY INSTALLATIONS.

At a recent soiree at Guy's hospital, London, the rooms were beautifully illuminated by Woodhouse-Rawson lamps, the current being derived from Faure-Sellon-Volckmar accumulators, which were delivered freshly charged in the morning. Although the work was merely temporary and but a short time allowed for completion, it was very well done, no wires being visible except where the lamps arranged as pendants hung down from the ceiling suspended by gold and red silk cord. The rooms lighted were as follows :—The Museum of Comparative Anatomy, a building 162 feet in length, was lighted by twelve 20 c.p. lamps, white reflectors being used to great advantage. The new museum was also lighted in a similar manner with nine 20-c.p. lamps. The entrance hall and staircase were very prettily lighted with suspended lamps, floral wreaths being used to form festoons from which the lamps hung. Each of the five rooms of the new ward had a distinctive style of lamp shade in order to harmonize with the decorations. In the first, blue venetian ; in the second, red and white ; in the fourth, white Dalsgrave and flat white opal shades alternately ; the fifth being used as a concert room, red and white shades were used. The centre room was furnished in antique style with special lanterns and electroliers.

The installation was made by Woodhouse & Rawson of London, who also exhibited a large collection of various electro-medical appliances.

UNDERGROUND CABLES FOR NEW YORK FIRE AND POLICE TELEGRAPHS.

The 170 circuits of the New York fire department, radiating from headquarters on Mercer street, are now connected with underground cables leading out for several blocks in each direction. Connections have also been made with Police headquarters by six special subterranean wires, and the Police News Bureau of the City Press Association at 301 Mulberry street, by three wires to each building. The Waring lead covered cable has been used for this work, it having been practically tested by the fire department and found satisfactory after 16 months service in different parts of the city. The recent work, which is the most extensive of its character yet undertaken by the departments, was started Saturday evening, October 24, and continued day and night without cessation until finished without interrupting street traffic. Superintendents Smith, of the fire department, and Crowley, of the police department, expressed themselves as greatly pleased with its successful completion.

DECISION AGAINST EXCLUSIVE RAILWAY RIGHTS-OF-WAY.

A contract between a telegraph company and a railroad company by which it is attempted to give an exclusive right to the former to build and operate a telegraph line over the lines and right of way of the telegraph company and by which the railroad company agrees to discriminate in the carriage and rates of freight against competing telegraph companies is absolutely null and void as being against public policy, according to the decision of the United States Circuit Court for the Eastern District of Louisiana, in the case of the Baltimore & Ohio Telegraph Co., vs. Western Union Telegraph Co.

DEATH OF EDWIN F. LEIGHTON.

Edwin Forrest Leighton who died at Boston, October 13, was one of the old school Morse telegraphers, familiarly known to the craft twenty years ago, as "Ned" Leighton, whose skill as an operator, and gentlemanly traits either in personal association, or over the wire, gave him a high standing among his fellow workers. His fine reputation secured his selection as manager of the Boston office of the old United States Telegraph Co., and subsequently of the Franklin line. He afterwards became night manager of the Western Union office where he remained until he assumed charge of the Baltimore and Ohio office last year. He always manifested great interest in politics, and as a democrat was elected to the legislature several years ago, from a republican district. He has also been elected and re-elected as an alderman, and at his death was a member of five standing committees of the board. Mr. Leighton was a native of Massachusetts, having been born at Lowell, December 8, 1840. He received a good common school education, with an academic course at Westford, and entered the telegraph service at an early age.

DEATH OF WILLIAM C. HICKS.

William Cleveland Hicks who died at Summit, N. J., October 20, has been identified with several important patent suits before the United States courts, as an electrical expert, having appeared in behalf of the McDonough interests against the American Bell Telephone Co., and for the Brush Electric company against Conduit, representing the United States Electric Lighting Co. He was the son of Rev. J. A. Hicks, of Rutland, Vt., and was born in New York, July 21, 1829. He was a graduate of Trinity College, and was the first city engineer of Hartford, having since been connected with various important engineering works. He was also prominent in the affairs of the Episcopal church, and was connected with the revision of the prayer-book.

ELECTRICAL TRANSMISSION OF POWER IN FRANCE.

At the meeting of the Academy of Sciences in Paris M. Deprez on October 27, reported that an experiment for the transmission of electrical power over a distance of 58 kilometres, between Creil and Lavillette, was a complete success. A 40-h. p. current out of 80 had been conducted over the line without the current heating the wire or the dynamo machine. Baron Rothschild paid the cost of the experiment.

ELECTIONS AND APPOINTMENTS.

The annual election of the trustees of the Edison Electric Light Company was held October 27, and the following chosen : C. D. Adams, C. H. Foster, Eugene Crowell, T. A. Edison, J. C. Tomlinson, A. Foster Higgins, E. H. Johnson, F. R. Upton, J. Hood Wright, Erastus Wiman, Spencer Trask, Charles Batchelor and F. S. Hastings.

ELECTRIC LIGHT AND POWER.

Domestic.

The Badger Electric Light Company is about starting its new station in Chicago, the power being supplied by two 150 h. p. Westinghouse engines, with two more to be added shortly.

An incandescent electric light company is soon to be established in New Bedford. The wires in the central part of the city will be put underground.

The Richmond Schuyler Electric Light Co. has been chartered in Richmond, with J. P. Branch, president; Andrew Pizzini, vice-president, and H. M. Sinnell, of Hartford, Conn , secretary and treasurer, to do a general electric light business, capital to be not less than $50,000 nor more than $250,000.

A company has been organized and the necessary capital raised for the introduction of a 600-light incandescent plant at Greeley, Col.

The Daft motor made another trial on the Ninth avenue line October 12th, with two cars and 100 passengers, from 14th to 53rd street and back again.

The Excelsior Electric Light Co., of Baltimore city, has been incorporated with John Q. A. Holloway, John W. McCoy, William A. Hanway and Sebastian Brown, of Baltimore, and Wm. H. Schock, of Washington, D. C., as directors. The capital stock is $300,000.

Foreign.

R. V. Strehleuert & Co., Sodertelge, have just established the first manufactory in Sweden for electric lamps. It is built in

Digitized by Google

the American style, and is managed by engineers who have had several years experience in the United States.

The first establishment lighted in its entirety by the electric light in Denmark is the beet-sugar manufactory at Nykjobing, on the island of Falster. The number of lamps is 200, of 16 c. p. each. They are manufactured at Mr. Forgenser's establishment in Copenhagen. The sugar manufactory is only in operation for the winter quarter, but the lamps will be needed from 14 to 16 hours out of the 24.

MANUFACTURING AND TRADE NOTES.

The Westinghouse Machine Co. have recently delivered engines for the following electric light plants:—Badger Electric Light Co., Chicago, two engines of 150 h. p. each; McKeesport Edison Co., fourth order for two of 100 h. p. each; Brush-Swan Co., Norfolk, Va., 75 h. p.: J. C. Reagan, Omaha, two of 60 h. p. each; Kaufmann Bros., Pittsburg, 60 h. p.; Cleveland Electric Light Co., fourth order for 60 h. p.; Ryan Hotel, St. Paul, Minn., 50 h. p.; Duluth Electric Light Co., two of 45 h. p. each; M. Brand & Co., Chicago, 45 h. p.; "Battle of Sedan," Cincinnati, 45 h. p.; John Shillito & Co., Cincinnati, 45 h. p.; U. S. Electric Light Co., Dubuque, 45 h. p.; McTighe Electric Light Co., Pittsburg, sixth order for 35 h. p.; Southern Hotel, Chicago, 25 h. p., also a number of smaller sizes.

Westinghouse, Church, Kerr & Co., of this city, have taken the contract for the motive power in the Edison station at McKeesport, Pa. The station already consists of two 50 h. p. Westinghouse engines, which will now be increased by two more of 100 h. p. each, with proportionate boiler power. Natural gas will be burned under the boilers, the furnaces of which are 40 inches deep below the shells.

E. S. Greeley & Co. have the contract for supplying the telegraph poles along the lines of the Shreveport & Houston and Houston, East & West Texas railways.

The Eddy Electric Mfg Co. of Hartford, succeed A. H. Eddy as manufacturers of the Mather dynamo-electric machines for electrotyping, electroplating, the reduction of ores, etc. The demand has necessitated increased facilities for the production of these dynamos.

The use of electricity for lighting gas, is being adapted to every possible branch of such work by the Electric Gas Lighting Co. of 45 Milk street, Boston, which by the manufacture of first-class goods and sagacious management is placing the business upon a solid footing.

The carbon point manufacturers of the United States met in Cleveland October 29, to form a combination for the advancement of prices.

MISCELLANEOUS.

The Howard Electric Time Co., New York, has been incorporated. Capital stock, $100,000.

RAILWAY SERVICE.

The Liemke Railway Signal Co., Waterloo, Ill., has been incorporated for the manufacture of the electric and automatic signal machines of Herman Liemke; capital stock, $10,000; Spencer Tompkins, William H. Highland, W. C. Rodenberger, H. Olendorph and Fred Joedke are the incorporators.

A very satisfactory test of the Waldermer electric brake has been made recently at Cincinnati. The current is generated by a small dynamo on the engine. The train, consisting of an engine and five cars, was stopped in 700 feet while running down a 68-foot grade at the rate of 45 miles an hour.

THE TELEGRAPH.

The National Printing Telegraph Company is to manufacture, operate, and lease telegraphic instruments, and to build or lease lines. Its capital stock is $1,000,000, divided into 10,000 shares. John Rooney, Abner McKinley, Mark W. Samuel, Samuel V. Essick, George H. Fearon, Louis J. Morrison, and William M. Denman are the incorporators.

The American Printing Telegraph Company has been incorporated by John C. Cruikshank, Lemuel K. McKinney, John S. Silver, Frederick Reed, and William P. Arnold, with a capital of $200,000, to acquire the ownership of telegraph, telephone, electric light, and electric device patents generally. It is to do business throughout the United States, but its main office is to be in this city.

THE TELEPHONE.

It is reported that Prof. J. R. Paddock, of Stevens Institute, has in his possession the original telephonic instruments of Philipp Reis, and has been engaged for some time with other scientists in testing their efficiency.

The Delaware Telephone Co. has been organized, with some of the leading men of the state at its head, which it is expected will lead to an improvement in the telephone service of southern Delaware.

At Evansville, Indiana, in a case where the Bell Telephone Co. had refused to furnish telephones upon applications made by merchants there with whom the agents of the company were not on good terms, Judge Garrett has decided that this is not just grounds for refusal, and that the telephone company is bound by the laws governing common carriers to make no discrimination between the different applicants.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER *by* Pope & Edgecomb, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From September 22d, to October 13th 1885 (inclusive).

Alarms and Signals:—*Watch Stand Alarm*, J. Burmann, 327,919, Oct. 6. *Telemetry*, C. L. Clarke, 327,527. *Annunciator*, A. E. Briggs, 327,997, Oct. 13. *Signal and Call Apparatus*, C. A. Smith, 328,148. *Alarm*, G. M. Williams, 328,166. *Telethermoscope*, F. W. Flint, 328,205.

Clocks:—*Secondary Clock Movement*, C. H. Pond, 327,897, Oct. 6. *Attachment for Winding Clocks in series*, same, 327,898.

Conductors, Insulators, Supports and Systems:—*Telemeter System*, C. L. Clarke, 327,526, Oct. 6. *Method of Operating Circuits in Telemeter Systems*, same, 327,657. *Manufacture of Sheathed and Insulated Conductors*, J. Tatham, 327,971. *Conduit*, H. F. Cox, 328,012, Oct. 13. *Structure to Occupy Streets*, R. R. Hazard, 328,027. *Time Signal Transmitting System*, J. M. Oram, 328,055. *Apparatus for Utilizing the Current Force of Water*, E. L. Brady, 328,147. *Junction Between Cabled and Uncabled Conductors*, E. T. Gilliland, 327,080, Sept. 29. *Underground Conduit*, G. S. Cox, 327,383, H. C. Spaulding, 327,466. *Underground Conductor*, Peter Mackin, 327,458, Sept. 29; H. C. Spaulding, 327,480, 327,481, 327,485 *Compound Cable*, same, 327,459, 327,476. *Anchor for Telegraph Cables*, same, 327,460. *Cable*, same, 327,461, 327,491, 327,492, 327,493, 327,494. *Insulating Compound for Cables*, same, 327,462. *Means for Protecting Conductors Underground*, same, 327,463. *Insulated Conductor*, same, 327,464, 327,467. *Means for Protecting Conductors from the Heat of Subterranean Steam Pipes*, same, 327,468. *Composite Cable*, same, 327,472. *Multiplex Cable*, same, 327,473. *Apparatus for Laying Underground Conductors*, same, 327,474, 327,478. *Pipe for Underground Conductors*, same, 327,475. *Splice for Conductors*, same, 327,479. *Conductor*, same, 327,482. *Subterranean Cable*, same, 327,483. *Submarine Cable*, same, 327,484. *Anti-Induction Cable*, same, 327,486, 327,487, 327,488, 327,489, 327,490. *Circuit*, same, 327,495, 327,496, 327,497. *Manufacture of Insulating Blocks for Conductors*, same, 327,465.

Commutators:—*Switch for Motor and other Circuits*, L. W. Stockwell, 326,603, Sept. 22.

Dynamo Machines and Motors:—*Current Regulator for Dynamos*, J. J. Wood, 326,894, Sept. 22. *Dynamos*, R. H. Mather, 326,575; E. Grauert, 327,790, Oct. 6; W. B. Smit and A. Pot, 326,796, Sept. 22. *Motor*, M. Immisch, 327,797, Oct. 6; E. W. Rice, Jr., 328,253, Oct. 13. *Floating Current Motor*, W. Main, 327,888, 327,889. *Current Motor for Dynamos*, same, 328,418, Oct. 13.

Galvanic Batteries:—*Electrode*, J. B. Odell, 327,582, Oct. 6. *Battery*, C. W. Holtzer, 327,878. *Cell*, E. M. Gardner, 328,208, Oct. 13.

Lamps and Appurtenances:—*Incandescent Lamp*, J. Nelson, 327,578, Oct. 6; C. G. Perkins, 326,584, Sept. 22; C. Heisler, 327,795, 327,495, Oct. 6. *Lantern for Electric Lamps*, S. Heiman, 326,979, Sept. 29. *Gas Lamp*, L. Julig, 327,089. *Head Light*, E. B. Cutten, 327,143. *Carbon Holder*, H. H. Levett, 327,282. *Arc* ... *Lamp*, J. G. Allen, 327,375; A. L. Fyfe and John Main, 328,022, Oct. 13.

Measurement:—*Cu*... *rent Meter*, J. J. Green, 327,391, Sept. 29. *Measuring Instrument*, E. Weston, ... 327,908.

Miscellaneous:—*Steam Go*... *vernor*, E. H. Amet, 326,933, Sept. 29. *Water Wheel Governor*, same, 326,934. ... *Process of Manufacturing Permanganates*, T. Kempf, 326,657, Sept. 22. *Att*... *chment for Dental Chairs*, C. A. Eisenhart, 326,357, Sept. 29. *Mercurial Ai*... *Pump*, A. L. Reinmann and C. G. Ott, 327,313. *Hydraulic Lead Press*, J. R... *bertson*, 327,317. *Magnet*, H. C. Spaulding, 327,469. *Machine for Winding Ma*... *gnets*, same, 327,470. *Valve Operator*, C. L. Clarke, 327,525, Oct. 6. *Magnet f*... *or Signals*, W. E. Davis, 327,536. *Bolt Releasing Device*, G. L. Henzel, 328,0... 30, Oct. 13. *Temperature Regulator*, C. A. Tucker, 328,156.

Protectors:—*Safety Device for Circuits*, E. ... Thomson, 327,039, Sept. 29: H. C. Spaulding, 327,498, 327,499, 327,500.

Railways and Appliances:—*Railway*, H. T. ... Clay, 327,381, Sept. 29; R. L. Cohen, 327,382: J. F. McLaughlin, 328,420, Oct. 13. ... *Signal*, F. I. Myers, 327,576, Oct. 6; W. A. Murray, 327,962. *Elevated Rail*... *way*, A. Jackson, 327,690.

Storage Batteries:—E. T. Starr and E. Eugene, 327,31..., Sept. 29. *Cut-Out for*, G. B. Prescott, Jr., 327,964, Oct. 6.

Tools:—*Wire Splicer*, J. A. Helvin and H. Van Hoevenbe... gh, 326,906, Sept. 22.

Telegraphs:—*Repeater for Quadruplex*, G. W. Gardani... r, 326,637, Sept. 22. *Telegraphy*, W. Maver, Jr., 326,880. *Means for Preventin*... *g False Signals on Reversals in Quadruplex*, F. Van Rysselberghe, 326,892. *P*... *rinting Telegraph Receiver*, C. M. Jordan, 326,989, Sept. 29: A. Wirsching, 327,... 911, Oct. 6. *Submarine Duplex*, A. Muirhead, 327,097.

Telephone Systems and Apparatus:—*Switch*, C. Whittle... ck and A. C. Knapp, 326,610, Sept. 22. *Magneto Telephone*, J. H. Rogers ... and J. Webb, 326,675. *Toll System*, H. Edmunds and C. T. Howard, 32...7,073, Sept. 29. *Auxiliary Mouth-Piece for Telephone*, C. A. Harrison, 327,3...3. *Telephone*, H. E. Waite, 327,625, Oct. 6. *Arm Rest for Telephone User*... s, F. G. Johnson, 327,692. *Telephonic Apparatus*, S. P. Thompson, 327,8...7. *Magneto Telephones*, J. F. Cole, A. H. Low, 327,887. *Line Wire for Mechanical Telep*... *hones*, J. F. Gilliland, 327,940. *Acoustic Telephone Exchange*, 328,243, Oct. 1...3. *Mechanical Telephone*, F. R. Shaw, 328,258. *Exchange System and Ap*... *paratus*, L. B. Firman, 328,305.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

NEW YORK, DECEMBER, 1885.

ANNOUNCEMENT TO OLD SUBSCRIBERS.

A HIGH class technical publication, such as we aim to produce, must necessarily depend for its success, in a great measure, upon the favorable commendation of its readers. In order to make a slight acknowledgment to our present subscribers for any efforts they may choose to exert in behalf of this journal, we offer the following schedule of rates for 1886:

For your own subscription and 1 new name	....	$ 5 00
" " " " 2 "	....	7 00
" " " " 3 "	....	9 00
" " " " 4 "	....	10 00

This offer will hold good until April 1st, 1886.

Very respectfully yours,

ELECTRICAL PUBLISHING CO.,
115 Nassau St., New York.

THE PROCEEDINGS AGAINST THE TELEPHONE PATENT.

IT was stated in our last issue that a number of applications, including a new one of the Pan Electric Telephone Company, the Globe Telephone Company, and divers others had been made to the attorney-general for leave to file a bill and bring suit in the name of the United States to cancel the 1876 patent of Alexander Graham Bell, known as the telephone patent. A bill was prepared by the counsel of the first named company at Memphis, and permission is asked to file this and other bills. The petitions having been referred to the department of the interior, a hearing was ordered by the secretary of the interior on October 31st at Washington, and on that day the counsel of the petitioners and of the American Bell Telephone Company appeared before secretary Lamar. Finding that the question to be discussed was likely to cover an extensive field of inquiry, the hearing was adjourned by the secretary until November 9th, when it was resumed, and thereafter occupied a full week. At the hearing, the counsel for the several petitioners put in their evidence in the form of numerous affidavits, to which the respondents, the American Bell Telephone Company, presented other affidavits in reply. The case was then argued at considerable length by the counsel on both sides.

The questions actually at issue in this contest are of the most vital importance to inventors, patentees and manufacturers, and may be formulated substantially as follows: First; Has the government the constitutional power to cancel a patent in any case; and, second; Assuming such power to exist, is the case now presented by the petitioners a proper one for its exercise? The grounds alleged by the petitioners for the cancellation of the Bell patent, as nearly as we are able to discover from the verbose, rhetorical and more or less contradictory allegations in the Memphis bill, are, first, irregular and fraudulent procedure in the patent office, whereby Bell obtained an unlawful knowledge of the contents of a certain caveat in the secret archives of the office, and interpolated the same into his own specification, thereby securing a patent in fraud of the rights of the real inventor; second, want of novelty in the apparatus or method by reason of the same having been invented by Philipp Reis, Antonio Meucci, and others, facts alleged to be well known to the applicant and to the world, but fraudulently concealed by him from the officials of the patent office and, third, collusion between the professedly opposing parties in the litigation of suits brought under the patent, and also in interference proceedings before the patent office, in which the title of the patent was involved, whereby the courts and the patent office have been induced to render improper and unjust decisions in favor of Bell. A great number of affidavits were presented by the counsel for the various petitioners, by which these charges were attempted to be substantiated. It may, however, be said at once that no proof worthy of a moment's consideration was presented tending to support the charge of fraud in the patent office. As to the question of want of novelty, no evidence was presented other than that which has repeatedly been considered by the circuit courts, with the exception of the affidavits relating to the claims of Meucci, which have not, we believe, been judicially passed upon. The evidence tending to show collusion was of little importance, with the exception of the affidavit of Professor Gray, and even this stated in substance little more than his own personal opinion on the subject; all the facts set forth by him in support of that opinion being already well known to those familiar with the course of litigation which has arisen under the Bell patent.

A review of the proceedings at the hearing, of which we give a very full abstract in another part of the present issue, shows in the strongest possible light the utter absurdity of attempting to determine the question of the validity of a patent by a proceeding of this character. The counsel for the petitioners, among whom were gentlemen of acknowledged learning, eloquence and ability, were placed at a manifest disadvantage by reason of their entire lack of familiarity with patent law and practice and with the technical procedure of the patent office, from which it re-

Digitized by Google

sulted that a large share of the evidence introduced by them, and of the points made in their arguments, were entirely foreign to the real question at issue. The counsel for the respondent, on the other hand, are well known to rank among the foremost, if indeed they are not the very foremost patent lawyers in the country. Secretary Lamar, who presided at the hearing, is a statesman whose learning and ability are too well known throughout the length and breadth of the United States to require any endorsement at our hands, and while scarcely any person could probably be found better qualified to appreciate and to pass upon the great constitutional questions involved in the case, yet as he himself frankly admitted, he possessed but little knowledge of the principles and practice of the law in reference to patents for inventions. It resulted from this state of affairs that the arguments of the counsel for the petitioners were, almost of necessity, devoted largely to vehement and vague denunciation of the "telephone monopoly" and of the personal acts of the inventors and patentees whose labors have given value to the property of the Bell company, based in a great measure upon a total misapprehension of the true bearing and relations of the evidence which they themselves had presented, so that at times a hearer was irresistibly reminded of the argument of Sergeant Buzfuz in the case of *Bardell* v. *Pickwick*. But in making a concerted attack upon the professional honor and integrity of the different counsel who have heretofore been employed against the Bell patents, particularly in the Dowd and Spencer cases, and in the interference proceedings before the commissioner of patents, the petitioners have transgressed the limits of ordinary decency. The case must be desperate indeed in which it becomes necessary to resort to measures of this kind. It may be that before these proceedings are ended, names hitherto honored among their fellow men will be covered with reproach, but we are not yet ready to believe that such men as George Gifford, Frederic Betts, or William Baldwin, will be found in the list. The main argument of the respondent was directed to the fundamental point of the unconstitutionality of the entire proceeding, and was pronounced by all who listened to it to be an able and convincing, if not unanswerable, presentation of that side of the question. The argument in defense of the essential novelty of Mr. Bell's invention, and in justification of the decisions of the United States courts which have been attacked by the petitioners, was also a remarkably effective one. It is not probable that a decision will be reached by secretary Lamar before we go to press. The petitioners profess great confidence that the result will be in their favor, but they nevertheless are understood to admit that they have received no intimation which would justify them in making a positive statement to that effect.

An important question may arise, in case it should be decided that suit may be brought in the name of the United States, as to whether the government or the complaining parties shall defray the expenses of the litigation, which will necessarily be very great. It was stated officially at the hearing, that the legal expenses of sustaining the Bell patent had already amounted to considerably more than half a million dollars. It is believed that the department of justice has no fund at its command which is available to defray any considerable expense arising from such litigation, while on the other hand there would seem to be a manifest impropriety in any arrangement whereby the counsel appearing in behalf of the government should receive their compensation from private parties. This however is only one of the numerous perplexing questions which are likely to arise in case these proceedings are carried beyond their present stage.

THE CONSENSUS OF THE INCOMPETENT.

A WOULD-BE sporting character, upon being asked why his horse did not trot a mile in 2:20, replied that there was only one difficulty, and that was that the time was not long enough for the distance. We respectfully commend the logic of this gentleman to the attention of our esteemed contemporaries who are indignantly inquiring why the electric wires in this city were not placed underground prior to November 1st, 1885. There is a certain class of people in the community, who not only believe that any end whatsoever can be attained by a sufficient expenditure of money, but that the time required to prepare the plans or to execute a work of this character, is a factor wholly unworthy of consideration. With a sufficient number of gardeners and an unlimited supply of fertilizers, they might with just as much reason expect to plant and harvest a crop of potatoes within twenty-four hours. Interested parties who have been actuated by selfish motives in their endeavors to force the electrical companies to bury their wires, are now equally anxious that their own particular plan should be adopted without discussion or delay. The persistent agitation of these parties, has, as they suppose, alone urged the movement forward step by step, and now, late in the fall of 1885, they anxiously inquire through the press, "why still delay?"

In the first place the Daly act of 1884 was notoriously defective in its provisions, a fact which was repeatedly pointed out by the electrical press. The supplementary act of 1885 by which the existing subway commission was created, although an improvement in some respects, merely authorized the board to receive plans from the existing electrical companies for the burial of their wires, in default of which the commissioners were empowered to "devise" plans of their own to carry out the provisions of the law. No limit of time is set for the completion of the "devising," in which work the commission is now engaged. Every electrical engineer had recognized to a greater or less extent, the formidable obstacles which must necessarily be encountered in perfecting a subterranean system suitable for the accommodation of all branches of electrical service in this city. The professional opinions of these experts, were, however, hastily assumed to have been given in the interests of the companies owning overhead wires. It may have been for this reason in part, at least, that three gentlemen were appointed on the commission who were presumably unprejudiced, and who at the time of entering upon their duties professed no technical knowledge of the subject.

After giving ample notice to the companies to file plans, the commissioners gave public notice that the plans of "inventors and others" would be received for consideration, the time being finally extended to October 15th. An undertaking of this character ought never to be actually begun

Digitized by Google

until a thorough investigation of the subject, has been made, and this is what we are assured will be done before a decision is reached.

The cities of Philadelphia and Washington have been visited in search of information, as a popular superstition exists that all electric wires are underground in those cities as well as in London, still it is doubtful if either of them contains as many miles of subterranean line in successful operation as exists in the city of New York to-day. Chicago is generally believed to offer the only example of an extensive and well organized system of underground wires, embracing all varieties of electrical service, and after the examination of this is completed, the entire field of practical and theoretical subterranean work, so far as this country is concerned, will be taken up for final consideration in connection with the requirements of New York.

The work that is being done in Brooklyn, however suitable it may be for that city, is not applicable to the important thoroughfares of New York, as it is not feasible to permit each company to lay down an independent conduit. This has been done heretofore, but to continue the granting of such franchises would without question ultimately lead to a complication of subterranean work which would be even more annoying than the present condition of affairs above ground, respecting which so many complaints are made.

PROFESSIONAL ELECTRICAL ENGINEERING.

The attention of our readers is directed to an article in another column which we reprint from the London *Electrician*, showing the illusory ideas prevailing in England as well as this country regarding the openings awaiting the trained electrical engineer, and the fabulous salaries attached thereto. The graduates of scientific schools who have pursued a course of electrical study are frequently disappointed at their reception by the cold world, and we have heretofore reminded them that their training should be considered an apprenticeship rather than the attainment of thorough practical knowledge of the profession. It is also well to add that at the present time the opportunities for engagements at a liberal compensation are by no means plenty, even for the best practical men. The development of arc lighting, telephoning and telegraphing offer few inducements to electricians. The future of incandescent lighting and the transmission of power is more promising, for the reason that such work must be planned and executed with scientific accuracy in order to lead to commercial success.

It is but a short time since the public interest in electrical development was awakened, soon followed by the establishment of courses of electrical engineering in various colleges and universities. The apparent demand for trained electrical experts was succeeded by a reaction when it was discovered that an ordinary machinist's apprentice at a dollar a day, or the steam engineer already employed for service in his own line, were equally capable of acquiring the necessary skill to operate the average electric lighting plant. The installation could be entrusted to the management of the manufacturer's agent and the casual lineman, with whose profound knowledge of electricity in all its branches most of us are familiar. Subsequent success depended upon the care with which the combustion of low-grade fuel was conducted in order to produce the most power for the least money.

This is the field in which electrical engineers are expected to find employment, and it appears doubtful whether it will be sufficiently extended in time to provide for the vast number of graduates who will be from year to year added to the existing supply.

Notwithstanding this condition of affairs, we are well aware that the scientific training of these young men is of great value, and in many cases proves a most important factor in leading up to a successful career, yet it will not remove all of the many obstructions which continually beset the path of the struggling wayfarer.

THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

A general meeting of the Institute will be held at the rooms of the American Society of Civil Engineers, 127 East 23d street, New York, on December 8, at 1 p. m., for the purpose of making certain amendments to the by-laws which have been prepared by a committee appointed for that purpose. As the points involved are likely to draw forth considerable discussion no papers are expected to be read, although if time permits there are various questions which may properly be brought up.

The endorsement of a universal wire gauge, if such action was in the direction of a reform, would doubtless give encouragement to those who have already devoted attention to this subject. Members and associates who propose to attend should be prepared to give as well as receive information, for it is the mutual exchange of ideas and experience which gives practical value to an organization of this kind.

The careful guarding of trade secrets is less commonly practiced than was the case previous to the advent of technical literature. The individual who is capable of inventing new methods, and practically applying them to advantage, gains a prestige among his fellow craftsmen which eventually proves of greater value, and gives far more satisfaction to the originator than the monopoly of a mere idea, which is liable at any time to be rendered valueless by the introduction of new processes. It is quite noticeable that many gentlemen well versed in electrical science, apparently prefer to present their views before organizations which are not strictly devoted to the subject. Many of these societies are older, and perhaps more widely known than the Institute, but we doubt if the benefits either given or received, are equal to those arising from association with actual co-laborers in the same field.

THE PHILADELPHIA DYNAMO TESTS.

The final results of the exhaustive tests of dynamo machines in connection with the Electrical Exhibition last year, have been published by the committee, and the report is a most important contribution to the investigations in this branch of the science. It was our intention to review the valuable work performed by the examiners, but as only a portion of the report could be published in the present issue, we have deferred our comments until its completion in the January number. The electrical community would no doubt be more thoroughly satisfied had there been a greater variety of dynamos in competition, as it is a most difficult matter to secure accurate tests, made under equitable conditions, the results of which may be accepted without question.

THE CONSTRUCTION OF LINES FOR ELECTRIC CIRCUITS.

BY THOMAS D. LOCKWOOD.

(Concluded from page 418.)

JOINTS in cables are by those who have to make them, technically called "splices," and making them may be divided into several complete processes, *i. e.*, joining the conducting wire; joining the insulation; joining whatever hemp, rope or other packing there may be; and finally splicing the armor. Happy is the cable constructor who does not at some point or time have to make a joint. I shall not attempt here a detailed description of the methods to be adopted in jointing rubber or gutta-percha cables, as it would necessarily be a transcript of what has already been fully described in many text books, but better I think in Swift's Practical Telegrapher, than anywhere else.

As the text books, however, devote their energies chiefly to jointing the insulation and armor, I have thought it well to devote a short space to the conductor joint. Where the conductor is composed of strand wires, these are first soldered together to form a solid wire, and the two ends are then scarfed down by filing as in the figure below, in which the two ends are shown as they appear after they are put

FIGURE 28.

together. When the two scarfed surfaces are thus joined, they are served with copper wire about No. 22 gauge, and the whole is once more soldered. Another serving of copper wire is then applied, extending beyond the first, and soldered at its ends only, so that if the joint opens out, the electrical continuity will still be maintained.

Another joint which is stronger although not so short or so neat, is made as follows:—The two lengths of cables to be joined are each given two or three twists by coiling on the floor, and the several wires of the strand being then unreeved, are each separately joined to a strand on the other side by scarfing as in the former case, and so as to break the joints, and two or three extra twists are then given to the entire joint by straightening the cable.

This splice takes a considerable length of bared wire; and cannot be employed in cables having single conductors. Joints for paraffine cables are referred to in the prior article on aerial cables.

UNDERGROUND LINES.

There is now so much public feeling upon this subject, and it is so freely canvassed by the daily press that to leave it without reference in this series of articles seems to be hardly prudent. It is by no means a new idea to lay electric wires below the surface of the earth.

Morse made his first attempt at electric telegraphy, with underground wires; Wheatstone and Cooke also attempted so to lay them.

Ronalds as early as 1816, laid electric wires encased in glass tubes in his garden, and passed messages through them.

The early attempts at burying conductors all however failed through defective insulation. There are at the present time several systems of telegraph working over underground wires, although complete telephonic systems with the exception of that of Paris have not as yet come into existence. There are a number of different plans for laying wires underground, and several hundred patents on the subject, most of which, however, relate to mechanical details of conduit, and arrangements for supporting the wires.

One well-known plan for burying telegraph wires is the one adopted by the German government for its telegraph lines. This is to prepare armored cables enclosing the required number of electric conductors, and to bury the cables direct in the earth without any boxing or troughing whatsoever. The German cables each contain seven copper conducting strands of 90 pounds to the mile, and insulated with gutta-percha weighing 76 pounds to the mile. The seven wires, each insulated, are placed in an armored sheath composed of 24 galvanized iron wires each about one-tenth of an inch in diameter. The weight of the iron is about 4,080 pounds per mile. The iron armor is then wrapped over for protection against oxidation, by jute impregnated with a bituminous compound. The entire weight of these cables is about 6,100 pounds per mile, while the breaking strain is four and a half tons.

These cables seem well adapted for their purpose, and if properly made at first, with regard to insulation, ought to be very durable. The operation of fast systems over them is perceptibly impeded when the circuits are long. But I think them, nevertheless, the best form of subterranean wires for long lines.

A second method which has been proposed, is to build chambers or vaults below the surface, and connecting each two chambers by iron tubes, pass insulated wires or cables through the tubes. This is the most expensive way—although perhaps the most durable. This is substantially the method adopted by the British telegraph department in passing their wires through the London streets, although instead of vaults, test boxes only, are used.

Still a third way is to dig a ditch of suitable depth, and laying an open box therein, stretch lead covered cables in the box, cleating them down, and finally to fill up the box with pitch, and then nail or screw down the cover, and fill up the ditch. The cables are thus led underground to suitable points where they emerge, and from whence their wires are distributed to their various points of destination.

This method may be varied by cleating the separate wires instead of the cables, but the results are by no means so satisfactory as the heat from the melted pitch is apt to run them together. Still another way is to take a multiple conductor cable heavily covered with lead, and to bury it without either box or armor. This answers well for short telegraph lines, but must not be laid in clayey soil, as the lead in such soils undergoes decomposition.

Each of these methods is much more expensive in first cost than an overhead system of equal capacity, and when they are used for any length with fast sending systems are harder to work over, and diminish the speed of working materially.

For private Morse lines, of no great length extending between few stations; for private telephone lines of not more than a mile or two in length, underground lines when well insulated answer well.

If I were running a line between a house and stable, or between two adjacent residences, for such purposes I would prefer the underground plan every time.

Where several lines are to connect the same points, a lead covered cable buried with or without boxing will do. For a single short line, not exceeding a couple of hundred yards, lead covered kerite or rubber covered wire is the best to use.

Wires centering at telephonic exchanges are not conveniently placed underground, as the retardation due to static induction shows itself on very short lines, and makes the talking very indistinct. This is quite perceptible even on a half mile line, and is much emphasized when a long line is connected thereto.

It is not likely that systems of telephone wires, and district messenger call wires can ever be placed entirely underground even though the electrical difficulties in the way should be totally eliminated, as the mechanical obstacles are almost insuperable, since the wires have to be brought out and distributed so frequently.

NOTES ON SOLDERING.

I have made frequent mention of soldering in the course of these articles—and it may perhaps not be amiss in con-

Digitized by Google

clusion to give a few hints on the necessary manipulations.

Soft soldering is that which is most generally applicable, and from the low temperature at which the solder fuses, it may be used in connection with almost any metal. The surfaces to be joined must first be cleaned. Iron and copper may be cleaned with a file or knife, or with emery paper or acid.

Lead, tin and pewter, may be scraped. Tin-plate and thin metals, may have soldering fluid placed on them and the solder then applied directly. Thicker masses of untinned metal, especially iron, should first be tinned by the application of a little flux, and a dipping in the solder.

When convenient the quickest way is to have the solder all ready melted in a ladle or melting pot, and to dip the fluxed joint completely into the fused mass, rubbing the solder well into it with the soldering iron. Taking it out, the joint may be squeezed a little to remove the superfluous solder, and then allowed to cool.

When a splice is so placed that it cannot be dipped; the flux may be first applied, and some small pieces of solder placed on the joint, and wrapped round with tinfoil, after which the flame of a Bunsen's burner may be, by means of a blow pipe, directed on the joint.

THE END.

LIABILITIES OF TELEGRAPH COMPANIES AS AFFECTED BY PRINTED CONDITIONS.

BY J. P. KIRLIN.

PART II.

In the November number of this review (at page 424), I dwelt on the question how far a telegraph company, by conditions in its blanks, can limit its liability for mistakes and delays in the transmission or delivery, or for non-delivery of messages, whether happening by negligence or otherwise; and presented the divergent views of courts of high authority upon that mooted subject. It was premised that such a company might, by special agreement with those who employ it, make reasonable rules and regulations regarding the operation of its lines, and that those regulations might sometimes work an exemption of liability for damage in some jurisdictions even when the loss occurred through negligence; that the sender of a message is not bound to comply with any regulation or accept any condition operating as a waiver of his right to proceed against the company, unless he chooses; and that he can, by process of law, compel the company to make an unconditional contract, under which the correct transmission of his message is insured. But the annoyance and expense of such a proceeding, and the desire to use the wires at once, usually deter employers from availing themselves of this right. They contract subject to the conditions imposed, and take the chance of overthrowing them in case the messages are improperly delivered. Assuming, then, that the contracts are so made, it is the purpose of this paper to examine into the force of certain other of these conditions.

1. A common provision is that "no responsibility regarding messages attaches to this company until the same are presented at one of the transmitting offices; and if a message is sent to such office by one of the company's messengers, he acts for that purpose as the agent of the sender." Applying the test of reasonableness and fairness to this clause, the courts allow it to be valid. It is a precaution that is wisely taken. The transmitting agent is possessed of information respecting the lines, which is wholly without the knowledge of a messenger, and it may be desirable for him to inform the sender of accidents and obstructions, making delay unavoidable, by reason of which a change of the terms of the contract is rendered necessary. So, also, he should be given an opportunity to obtain from the sender, whatever information he wishes respecting the message, and, if a breach of the contract be probable, the amount of damages such breach will entail. Reason and authority both make in favor of upholding this condition, and as pains are taken to have transmitting offices everywhere accessible, it appears to be without serious objection.

2. A regulation requiring the sender of a message to disclose its true import, is deemed to be unreasonable, and cannot be enforced. It cannot be claimed that a full knowledge of the meaning of a message is requisite to its correct transmission. All that an operator requires is plain words, plainly written. To allow the enforcement of such a regulation, would be to encourage agents in impertinent inquiries relative to private affairs; and moreover would operate as a serious check on the free communication of intelligence. A company cannot require such a disclosure even where it is suspected that a message is immoral in its purposes, if it be not immoral upon its face. It has been held that there is no provision of law which authorizes a telegraph company or its agents to question or impugn the motives of anyone who might wish to transmit over its wires, a message couched in proper and decent language. And there is certainly no law which constitutes the agents of a company the censors of public morals, or permits them to pass upon the good or bad faith of individuals who choose to forward dispatches over its lines. If only the message be couched in fair language, the duty of the telegraph company, on payment, or tender of the legal tariff, is clearly fixed by law. It has no discretion but to send the message. If, however, it be expressed in obscene or improper language the company is excused from the duty to transmit.

3. A regulation that messages will not be received in time of strikes, except subject to delay, may or may not be valid according to circumstances. If the company, from such a cause, is induced to limit, in some public manner, the scope of its business, and if in a reduced sphere, it serves fairly those who wish to employ it, it may refuse to send a dispatch, save subject to delay, by reason of this clearly specified cause; and will not be liable to an action for such refusal. But inasmuch as the primary function, indeed the *raison d'être* of a telegraph company is to effect the rapid transmission of intelligence, any stipulation or exemption in derogation of this purpose, must be specifically stated. It cannot, accordingly, demand to send "subject to delay," simply. This expression is broad enough to include wilful, or negligent delay, either of which does violence to the very nature of the company's calling.

4. A condition that "the company will not be liable for damages in any case where the claim is not presented in writing within sixty days after sending the message" is everywhere upheld as reasonable and valid. There are strong considerations in its favor. It must be borne in mind that it does not debar the sender from bringing his suit any time within the period of the statute of limitations (usually six years). The company only demands that it be advised of the existence of a claim, with particulars of its extent, while the transaction is still fresh in the minds of all concerned. It may easily happen in a large office, where much business is done, and the help frequently changed, that in a comparatively short time the circumstances attending a particular transaction would sink into oblivion, and the defense of a stale claim thereby made practically impossible. Moreover, the companies are often willing, for business reasons, to pay a clearly established loss, and therefore claim to be informed thereof at an early day, in order to conduct their own investigations and discover where among their employés the blame is to be placed. As it simply requires the exercise of that diligence which an ordinary individual would naturally show in a case of real damage, there can be no well sustained objection to its fairness, while from the sender's own standpoint there is much to be said in its favor.

5. A condition that the company will not be liable in

case of mistaken delivery, or for non-delivery where occasioned by negligence, we have seen is destructive of the agreement to transmit and is therefore inoperative. The essence of the company's agreement is to deliver the message promptly, and to the person to whom it is addressed. Diligent efforts must therefore be made by the company's agents to find the right person ; and if these fail, the message must be mailed to him at the address given ; it being presumed that the postal authorities have a record of the addresses of persons who have moved, or are absent from their customary abodes. The company is always liable for delivery to a person other than the one intended. But it is not liable, if delivery be made to an impostor, if the sender was ignorant of the imposture, and in his ignorance intended the message for him. A curious case illustrative of this arose in Alabama. X telegraphed to A's uncle in A's name, asking for a telegraphic money order. The unsuspecting uncle telegraphed the order, addressed to A, at the place whence X had telegraphed, which was not A's habitual dwelling place. X received the message, and obtained the money. The uncle, on discovering the imposture, sought to hold the telegraph company, on the ground of delivery to the wrong person. But the court held that the delivery was good. At the first blush this appears to be an extreme case, but on more consideration it will be found the right view. Suppose, for example, that the uncle had detected the fraud and had sent the order asked for as a decoy to entrap X, and that the company's agents also knowing the truth, but ignorant that the sender had discovered it, assumed not to deliver the message, or had delayed delivery in order to communicate with the sender. However praiseworthy the motive, this action might undoubtedly be treated by the sender as a breach of contract. It was a delivery to the person whom both parties to the contract intended should receive it ; and in this view the contract was, of course, performed and the company thereby exonerated.

6. The question has arisen whether a telegraph company, as a condition of sending a message which on its face requires an answer, can demand a deposit by the sender as security for the service to be performed in transmitting the reply. The Western Union company has such a rule provided by its by-laws, and under this rule a curious case was recently determined in the state of Indiana. A transient person presented a despatch at the transmitting office, which, in terms, requested an answer; and the operator having refused to place it on the wires, unless a deposit was made to cover the charge for an answer of ten words, an action was brought in which the validity of the rule was considered. The argument of the sender was, that he only invited the company to send his own message; that his request for an answer was a request for the performance of services by his correspondent, and not by the company; and that accordingly the demand for a deposit was wholly without legal warrant. The company, however, successfully contended that it was unreasonable to assume that the sender would ask his correspondent to furnish the information desired, and also to bear the expense of its transmission; and that as there was in effect, a request for the company to perform a further service, the rule requiring a deposit to cover such service was reasonable and valid. The court in delivering judgment said : "We are unable to perceive anything unreasonable in the by-law under consideration. A person who sends another a message, and asks an answer, promises, by fair and just implication, to pay for transmitting the answer. It is fairly inferable that the sender who asks an answer to his message, will not impose upon the person from whom he requests the answer, the burden of paying the expense of its transmission. The telegraph company has a right to proceed upon this natural inference, and to take reasonable measures for securing legal compensation for its services. It is not unreasonable, unnatural, or oppressive, for the telegraph company to take fair measures to secure payment for services rendered; and in requiring a transient person to deposit the amount legally chargeable for an ordinary message, it does no more than take reasonable measures for transmitting the asked and expected message. We have found no case exactly in point, but we have found many analogous cases, which in principle sustain the by-law before us." And so it was upheld.

ELECTRICAL ENGINEERING.[1]

A LAMENT FOR THE ELECTRICIAN.

The profession of "electrician" is fast assuming the unfortunate garb of too many of our trades and professions. It is already, like these, filling the advertising columns of not only its own scientific journals with situations and appointments wanted, but has found a level amongst the clerks and commercial agents seeking any suitable employment rather than find themselves without home or food. What a dreadful come down, indeed ! A profession ranking side by side and carrying the same importance as that of the civil engineer; a profession requiring a wide and varied scientific knowledge, coupled with a mathematical and inventive brain-power; a profession considered perfectly suitable, and, indeed, studied by gentlemen of birth and education, to have reached such a depressed state that even those who have made its mysteries a life-long study, and taken pleasure in doing their best to advance its infant steps to strides of magnitude, now find their hopes crushed, their energies all but wasted, their livelihood quickly disappearing, and their repeated appeals for electrical appointments utterly disregarded. This not only applies to the junior members of the profession, but it is within our knowledge that men ripe in the theoretical truths of this natural, but seemingly unnatural, agent, and experienced beyond a doubt in its practical applications, past holders of important and responsible posts, are at this moment seeking work to do. Their hands, in the past used to the manipulation of telegraph instruments and other electrical apparatus, are now forcibly obliged to be idle, whilst their ready money is expended in repeatedly advertising their talents and consequent requirements. These advertisements appear and reappear, first in one journal then in another, and latterly it has been literally grieving to see that the daily advertising media have received a share of this unfortunate patronage. Unmistakeably the profession has received a terrible blow, a disaster has befallen it so damaging to its young life that it now practically walks on crutches. Such a fate spreads trouble broadcast, as during the last five years the electrical profession has gained such vast importance that the time has been also prolific in the manufacture of students and practical men. These men, as electrical engineers, have found, and still find, their time fully occupied, as they can never finish or neglect to apply themselves constantly to its studies. The scope of these studies involves most engineering subjects, widening almost daily by the importation of new theories and the ever increasing inventions for its practical applications; indeed, electricians find it impossible to be all-round men, or profess proficiency in every branch, as its thousand and one commercial industries are beyond an individual brain. Employment, time, and experience may presently prove merciful enough to attain such an enviable consummation, but specialists are now the order of the day—specialists for special branches, to the lock-out of intruders. Telegraphy and its partisans can swim along easily and successfully because of its riper years, but the newly-initiated electric light and telephony are suffering much. The telephone is chained hand and foot and hampered against competitive improvement by the iron hand of monopoly; whilst electric lighting has been nipped in its budding life and its earlier successes completely smothered by the overwhelming selfishness of a few untutored adventurers, who sought to, and did, enrich themselves at the

1. The *Electrician* (London).

Digitized by Google

expense of the most brilliant of domestic commodities. Necessarily its votaries are the immediate sufferers; its admirers have undoubtedly suffered by loss of money, and the general public are suffering from their general mistake. There are some engineering electricians whose pecuniary means enable them to defy commercial depression, and there are even those amongst them, unfortunately, who at this moment actually gloat over the loaded neck of the half-drowned industry, because it gives them time to advance their particular branch by strides, and to insure, perhaps, a monopoly in the future, or to raise their chances in the electrical resurrection. These find enough work, in the absence of competition, to keep them going at a fairly brisk rate. Not so the less favored; they may starve or betake themselves into the whirling lottery for other employment. Now, what is the cause of this state of things? What circumstance is it that within this short space of time has so completely overturned the brilliant prospects of a superior profession, and been the means of beggaring many and stultifying others? The answer is—legislation and speculation.........English commerce and competition are ever on the increase; continually some new theoretical problem is being thrashed into workable condition, and mental activity giving birth to new scientific applications. But in electric lighting is found a commodity which, having reached a certain political point, received a stunning blow, the effects of which will require time and patience to overcome. Some years since American industry lent its fascinating charms to simplify and overcome the difficulties experienced in this country in the manufacture of machinery necessary for the production of the electric current, and also the means for utilizing its energy. Other countries also brought assistance, until our English market was enabled to offer a fairly good assortment of dynamo machines, lamps, and apparatus, intended to revolutionize the existing lighting system, with which people had been familiar for the last 50 years. Necessarily a commotion followed. The public mind became a whirlpool, and excitement increased step by step with the advancing strides of this giant illuminating competitor. Gas shares and dividends were scrutinized, whilst its manufacture became a question of general interest for improvement. It was at this time that gentlemen's sons, finding an occupation opening to them compatible with their social standing, and embodying a professional career, sought eagerly for centres of instruction, and paid heavily in order to be first in the field. Several enterprising capitalists immediately lent themselves and their money to this evident source of profit, with the result that more would-be electricians were turned out than were even then necessary. A few *bonâ fide* corporations were hard at work doing their best to render the new scientific industry a commercial success, and employing both time and money in research simultaneously with active work. As the public confidence was yet wanting, few installations were made, and these few were individual and isolated, for the simple reason that customers could only be found amongst large consumers of gas, and whose calculations taught them that a saving might be effected by the employment of a larger illuminating agent. The manufacturing districts of the midland and northern counties afforded the largest sphere for the efforts of the electrical engineer. Sheffield, for instance, at that time could boast of the greatest use of the electric light. Its enormous iron and kindred works were enabled to continue their work both by day and night; but here it is only fair to say that the commercial value of electrical apparatus was anything but perfect, and consequently its employment in these particular cases was a continual source of professional anxiety. Trained electricians were attached to these individual installations, and, as a matter of fact, found themselves well occupied in constantly adjusting some provoking portion of the circuit whose performances popped here and popped there like the caperings of a jack-in-the-box. The energies, and temper, perhaps, of the electrician might well find cause for compulsory rest after a long spell of such care and anxiety daily, from perhaps four o'clock in the afternoon until eight o'clock the next morning, during the coldest of winter months, continually watching that no failure placed works and workmen in darkness and danger. Such, indeed, has been experienced, and even a ladder kept ready at any moment to mount and arrange refractory carbons or sticking cut-outs.

With an extraordinary commercial foresight and adaptability, one or two particular companies, obtaining patent rights, and representing the manufacture of a specific system, hurriedly obtained quotations for their shares upon the stock exchange, and surprised both the electrical and commercial world by their sudden activity in preaching the surprising merits of their own wares. Enterprise and duplicity were not wanting. No trouble was spared to excite the public mind to a state of frenzy, and undoubtedly such efforts were rewarded, much to the detriment of both people and enterprise. Undoubtedly the public were duped, whilst those behind the scenes, the instigators of so foul a bubble, laughed in their sleeves. Company shares were run up and concessions sold to subsidiary companies, whilst promoters quietly and greedily pocketed a first-rate income. One or two, personally known, could pocket their thousands in a week. The stock-brokers were exceedingly busy, shares continually changed hands, money was lost and money made, until the speculative epidemic seemed to have laid a siege and so bombarded the excitable commercial susceptibilities of the business man that no room was left to listen to the warning voice of the reasoning electrician, who foresaw the imminent evils of such precipitate action. The sequel followed, a review of which commenced with the subsidiary companies being thrown for the first time upon their own resources. To find legs wherewith to stand appeared to be a matter of great difficulty to not a few of them after the vast expenditure entailed in the purchase of the right and its conveyance. Starting with brilliant hopes, excited determination did much to render those in office obdurate to the difficulties before them. Such matters had not been considered, and there was not time now to look at the stern matter-of-fact duties that lay before. In some cases a large amount of capital was spent in building central stations with the idea of supplying householders with domestic electric lighting from the one centre, and upon the same mains as the public lighting of the streets, whilst others wasted their substance in some other imprudent or riotous commencement to their existence. It must have come upon them as a depressing fact that, coincident with their finding out the many difficulties with which they had to contend, arising partly from the incomplete condition and unsuitability of their electrical apparatus, and the want of money, the public enthusiasm seemed to be abating, that the quotation of shares was gradually ebbing out its life, and that the great speculation agitators, finding their game played out, were taking back places and otherwise finding refuge in obscurity. Then, and not till then, came upon these subsidiary companies the realization of their position; foundations built on the sand, with not even a pecuniary backbone as a prop; public enthusiasm dead; scientifically insufficient and inefficient tools to work with; a one-sided and unworkable act of parliament of rights and restrictions, and no money; a chaos of disasters, being a death blow to any enterprise whatsoever. Failure followed, and, one by one, each found its way into the list of voluntary or compulsory liquidations; and, as a calm always succeeds a storm, so a terrible period of inactivity in the electric lighting commercial industry has proved no exception to the rule. For the last two years the majority of electricians have found their services immensely at a discount, and many have even had difficulty to subsist. Of the public installations, which had been almost considered as permanencies, some have died, and others are gradually disappearing. Even the Thames embankment falls back

Digitized by Google

upon its old friend and faithful servant, whilst the city lighting has resolved itself into a few straggling and struggling old type, perhaps half-discarded, Brush lamps. Into what a state of collapse has it descended! Into a bottomless pit? Well, hardly as far as that. Resuscitation has yet a chance, and will step in; but when? is the question.

MINIMUM E. M. F. IN TRANSMITTING POWER.

BY PROFESSOR H. S CARHART.

THE prominence attained by recent practical experiments in the electrical transport of power justifies the fullest theoretical discussion. Any light that theory can throw upon the subject must be of some value. I shall therefore attempt to make clear the question of minimum E. M. F. that can be employed under defined conditions, even at the risk of being too mathematical for some readers.

So far as observed the discussions of the general problem have proceeded upon the following basis: Given the E. M. F. of the generator and the resistance in circuit, to find the *maximum* rate of working, or the maximum work that the motor can do. What I propose is, given the resistance in circuit and the work required of the motor, to find the *minimum* E. M. F. This latter is the form in which the matter presents itself as a practical problem. I shall first give the usual solutions corresponding to the former conditions, and then the new solutions with the latter defined ones. In each case R and C denote resistance and current strength, E and E_1 the direct and counter E. M. F. of generator and motor respectively, and W the work done by the motor per second.

First. Given E and R to find C and *maximum* W.

a. Algebraic solution. The total energy of the current is divided into two parts, one of which goes to heat the conductor, and the other is absorbed by the motor and converted into useful work. Hence

$$C E = C^2 R + W \qquad (1)$$

The solution of this equation of the second degree is

$$C = \frac{E \times \sqrt{E^2 - 4 R W}}{2 R}$$

Plainly $4 R W$ cannot exceed E^2, or C would have an "imaginary" value, which is impossible. W will therefore be a maximum when $4 R W = E^2$. Hence,

$$W = \frac{E^2}{4 R} \text{ and } C = \frac{1}{2} \frac{E}{R}$$

The current for maximum work is therefore reduced to half the value it would have with the motor at rest, and $E_1 = \frac{1}{2} E$. This is known as Jacobi's law. It is not the law of efficiency but of maximum activity.

In the above values W and C are expressed in given terms; and we have the further deduction that for maximum rate of working the counter E. M. F., of the motor equals half the direct E. M. F. of the generator.

b. Solution by the calculus. By transposition of (1)

$$W = C E - C^2 R \qquad (2)$$

Whence $\frac{d W}{d C} = E - 2 C R = 0$ for the *maximum* value of W, since the second differential is negative. Therefore

$$E = 2 C R \text{ and } C = \frac{1}{2} \frac{E}{R} \text{ as before.}$$

The value of W may be found by substituting the value of C in (2).

Second. Given W and R to find C and *minimum* E.

a. Algebraic solution. The work done by the motor is

$$C E_1 = \frac{E_1 (E - E_1)}{R} = W \qquad (3)$$

If W and R are constants then is $E_1 (E - E_1)$ a constant also. Now when the product of two terms is a constant their sum is a minimum when they are equal to each other. But the sum of E_1 and $E - E_1$ is E, the E. M. F. of the generator. Hence E is a minimum when E_1 equals $E - E_1$, or $E_1 = \frac{1}{2} E$. This condition corresponds to Jacobi's law as might have been inferred directly, because the conditions determining maximum rate of working with a given E. M. F. must also define the minimum E. M. F. required to do a given amount of work.

To determine E and C in terms of W and R, substitute for E_1 in (3) its value $\frac{1}{2} E$, and we have

$$E^2 = 4 R W, \text{ or } E = 2 \sqrt{R W}.$$

$$\text{Whence } C = \frac{1}{2} \frac{E}{R} = \sqrt{\frac{R W}{R^2}} = \sqrt{\frac{W}{R}}$$

b. Solution by the calculus. From equation (1)

$$E = C R + \frac{W}{C} \qquad (4)$$

Whence $\frac{d E}{d C} = R - \frac{W}{C^2} = 0$ for *minimum* value of E, since in this case the second differential coefficient is positive. Hence

$$R = \frac{W}{C^2} \text{ and } C = \sqrt{\frac{W}{R}} \text{ as before.}$$

Substituting value of C in (4) and

$$E = 2 \sqrt{R W}$$

$$\text{Also } C E_1 = W \therefore E_1 = \frac{W}{C} = \sqrt{R W}$$

Therefore $E_1 = \frac{1}{2} E$ as above.

It appears, therefore, that the E. M. F. varies as the square root of the resistance. Hence, if any reduction of E. M. F. is attempted by reducing the resistance, the reduction of the latter must be much more rapid than the former. If R is reduced to one-fourth, the E. M. F. is reduced only to one-half. But the resistance may be increased fourfold by merely doubling the E. M. F., the same amount of work being done with the same efficiency. Whenever attempts are made to work with low E. M. F., as considerations of safety demand, then difficulties at once present themselves. The above discussion shows that with the requirement of a given amount of work to be done by the motor, the E. M. F. has a minimum value which cannot be reduced except by an inordinate and impracticable reduction of resistance.

To apply the results to a concrete example. Assume twenty locomotives on a New York elevated road to represent 2,200 h. p. If the electric motors replacing them have an intrinsic efficiency of 90 per cent., in round numbers 1,800,000 watts of energy must be supplied to the motors per second. If the resistance in circuit is 0.072 ohm, then

$$E = 2 \sqrt{R W} = 2 \sqrt{1{,}800{,}000 \times 0.072} = 720$$

$$\text{and } C = \frac{W}{R} = 5{,}000$$

With an assumed resistance of about three-quarters of an ohm the minimum E. M. F. required to transmit to the motors 2,200 h. p. is 720 volts, and the current is 5,000 ampères.

COMPETITIVE TESTS OF DYNAMO ELECTRIC MACHINES.

REPORT OF THE FRANKLIN INSTITUTE COMMITTEE.

To the Board of Managers of the Franklin Institute:

GENTLEMEN :—I herewith transmit the report of the Committee of Judges, consisting of Louis Duncan, Ph.D., Ensign, U. S. Navy, Chairman ; William D. Marks, Whitney Professor of Dynamic Engineering, University of Pennsylvania ; George L. Anderson, Lieut. U. S. Army, Instructor of Mathematics, U. S. Military Academy, West Point ; J. B. Murdock, Lieut. U. S. Navy ; A. B. Wyckoff, Lieut. U. S. Navy, Hydrographic Office, Philadelphia, appointed under authority of the resolution of the Board, adopted November 12, 1884, to conduct competitive tests of dynamo-electric machines, entered for competition by the Edison Electric Light Co., and the United States Electric Light Co., who duly accepted them as judges.

It was found impossible to constitute the committee from the list of names in the adopted code, most of those gentlemen declining to serve, or accepting under unavailable conditions.

Commander Jewell, U. S. Navy, acted as chairman at the beginning, and rendered valuable assistance and advice in the preliminary preparations. Owing to unavoidable delays, however, the tests were not begun before his paramount duties at the U. S. Torpedo Station compelled him to withdraw.

The conditions of the code were severe upon the judges, requiring protracted runs of the machines, and immediate calculations of results. The labors of the committee were therefore incessant, and were performed with such zeal, intelligence, fidelity, and success as to satisfy me that no praise of mine could exceed that to which a careful examination of the report of their work will entitle them.

The thanks of the Institute are due not only to the judges, but also to the heads of the departments and bureaus of the navy and army, whose consent was necessary to enable the officers to take part in the work.

The Institute is under especial obligations to the Johns Hopkins University for the use of their laboratory and for assistance in comparing thermometers and resistances.

The thanks of the Institute are also due to various parties for loans of apparatus, as follows :

Baldwin Locomotive Works, for use of boiler ; Buckeye Engine Co., Salem, O., for steam engine ; Professors Genth and Sadtler and the department of dynamics of the University of Pennsylvania, for platinum crucible, indicators, resistance coils and galvanometer ; U. S. Coast and Geodetic Survey, for magnetometer ; Stevens Institute of Technology for tangent galvanometer ; Mr. Wm. Harpur, for chronometer ; Mr. Henry Trœmner, for delicate balances ; Messrs. Fairbanks & Co., for beam, platform scales and standard weights ; Electrical Supply Co., of New York, for voltameter ; Commander Jewell, U. S. Navy, and the members of the committee, for the use of their instruments.

Very respectfully,

W. P. TATHAM, *President.*

PHILADELPHIA, September 26, 1885.

RESOLUTION.

[*Resolutions of the Board of Managers*, Nov. 22, 1884.]

WHEREAS, Through delay and lack of time on the part of many of the examiners, several of the largest exhibits at the Electrical Exhibition have had either incomplete examination or have had none at all ; therefore, be it

Resolved, That the president be directed to take such steps, appoint such committees, and incur such expense, not exceeding three thousand dollars, as shall be necessary to complete in a satisfactory manner the examination of exhibits.

MR. W. P. TATHAM, *President of the Franklin Institute:*

SIR :—I have the honor to herewith transmit the report of the committee appointed to conduct the competitive tests of the dynamo-electric machines of the U. S. Electric Light and Edison companies.

I am, very respectfully yours,

LOUIS DUNCAN, *Chairman.*

COMPETITIVE TESTS OF DYNAMO MACHINES.

On first organizing the committee, Commander Jewell, U. S. N., was elected chairman, but after directing some of the preliminaries, he was compelled to resign in order to resume his duties at the U. S. Torpedo Station, at Newport.

The tests were conducted under the following code, agreed to by the contestants :

Proposed Code for Test of Dynamo-Electric Machines to be used by the Franklin Institute of the State of Pennsylvania.

SECTION I.

GENERAL CLAUSES AND CONDITIONS.

(1.) The parties hereto subscribing do agree to accept the services of the examiners herein named, and to abide by the verdict of the judges and the methods of testing named without appeal from the decision reached.

LIST OF JUDGES.

(*From which five shall be chosen to act.*)

(2.) Prof. WM. A. ANTHONY, Cornell University, Ithaca, N. Y.
Prof. WM. D. MARKS, University of Pennsylvania, Phila., Pa.
Prof. J. E. DENTON, Stevens Institute, Hoboken, N. J.
Prof. W. E. GEYER, Stevens Institute, Hoboken, N. J.
Lieut. J. B. MURDOCK, U. S. N., Philadelphia, Pa.
Ensign LOUIS DUNCAN, U. S. N., Johns Hopkins University.
Lieut. JOHN MILLISS, Light-House Board, New York.
OSCAR BUSSMANN, Assistant.

(3.) The Franklin Institute will procure instruments, pay expenses of observers. The companies will pay for handling machines, running lines, placing and erecting lamps, and care for machines during test.

SECTION II.

CONSTRUCTION OF THE MACHINE.

(4.) The following data will also be given :
- Diameter of armature ;
- Weight of machine ;
- Number of commutator bars ;
- Turns and length of wire in armature coils ;
- Whether brushes must be adjusted, or are automatic for different currents ;
- Diameter and length of bearings ;
- Number of turns per minute ;
- Number of volts for best work ;
- Number of ampères for best work.

SECTION III.

PRELIMINARY TESTS.

(5.) The resistance of the field magnet coils and of the armature coils will be measured as follows : A strong current from a secondary battery shall be passed through these coils and ampère-meter and sensitive voltameter used to determine current and fall of potential. The resistance will be determined from these measurements. As an additional precaution, a strip of german silver of known resistance shall have its fall of potential measured with the same current and instruments. These measurements shall be made before and after the tests, with the machine hot and cold.

INSULATION RESISTANCE.

(6.) Tests will be made of the insulation of the terminals of the machine from its metal bed-plate.

Tests will be made of the insulation resistance between the commutator and the axle.

(7.) It is understood between the parties that if any mechanical defect is observed, another machine may be substituted if the committee agree that such defect exists.

The competitors shall have reasonable opportunity to obtain information of the progress of the tests, and to know the figures of each test for the object of ascertaining errors in time for correction.

The observations made will be publicly posted before the machine is removed from the dynamometer.

CALIBRATION OF INSTRUMENTS.

(8.) The constants of all instruments used shall be determined by at least two independent methods. The companies shall have opportunity to inspect and observe the methods used and shall be furnished with the constants of the instruments immediately after they have been determined. All objections to the methods used

Digitized by Google

will be received and acted upon as provided under Section IV., Article 17.

SECTION IV.

QUANTITATIVE TESTS.

(9.) The dynamo to be tested will be run under full load for ten hours continuously, to see that all is in good working order before the tests begin.

(10.) For the actual test the machine shall be run and the temperatures of the pole pieces and armatures observed until a uniform temperature is reached.

(11.) When a uniform temperature for each load is reached, the measurements of power shall begin.

(12.) The machine will be tested on both live and dead resistances.

(13.) The machine will be tested on one-quarter, one-half, three-fourths, and full load. In the latter case to be run at least five hours after a uniform temperature is reached.

(14.) Full measurements of friction and of energy expended in field will be made in each case.

DYNAMOMETRIC MEASUREMENTS.

(15.) The shaft of the dynamo will be directly attached to the end of the shaft of Tatham's dynamometer, by means of a universal joint coupling, and the horse-power used read from the dynamometer, unless the committee, for reason, shall decide otherwise.

OBSERVATIONS.

(16.) The observations on the dynamometer, current galvanometer, and potential galvanometer, and all other instruments, will be taken at synchronous intervals.

The temperature of the room will be made as even as possible, and the temperature noted and necessary corrections made.

The adjustment and oiling of machines shall be in the hands of the authorized expert for the company.

(17.) In case any objection be made, or difference of opinion should arise between the committee and the contestants, the unanimous vote of the committee shall be final.

If, however, there be not a unanimous vote, the minority of the committee shall appoint one referee and the majority another, these two shall appoint a third referee.

The decision of the majority of these referees shall be final.

In all determinations of efficiency of machines, measurement of potential shall be made (simultaneously with measurements of the current strength) at the binding posts of the machine, and at such other points of the circuit as will determine the total fall of potential, due to the resistance of the leads, connections and switches included in circuit with the instruments used for determining current strength. From these measurements, the loss shall be calculated and credited to the machine under trial.

[Signed] FRANCIS R. UPTON.
United States Electric Lighting Company per EDWARD WESTON, *Electrician.*

Figure 1 gives the general arrangement of the apparatus. The test room, in which most of the instruments for electrical measurement were placed, was in about the middle of the exhibition building of the Franklin Institute. The dynamos, with the boiler and engine used in running them, were in a shed at one corner of the building; and the resistances for their external circuit—lamps and german silver strips—in a room inside the building and very near the shed.

The storage battery, tangent galvanometer for current calibrations, and galvanometer for measuring field currents, were in different parts of the building, far enough from the test room not to affect the instruments in it.

The leads from the dynamos and storage battery, and to the tangent galvanometer were of heavy, insulated copper cable. They were taken to the corner of the test house farthest from the instruments, and where they approached it the two parts of a circuit were twisted together, one of them being covered with rubber tubing as an additional precaution against leakage. Even with the heaviest currents (about 400 ampères) there was no effect on the instruments, and calibrations made both when the dynamos were and were not running, showed that any disturbance from currents in the leads had been avoided.

Before any measurements were made, the insulation resistances between the leads themselves, and from the leads to the ground, were carefully tested and found in every case to be over 50 megohms; and measurements at intervals during the tests showed that they remained about the same.

OBSERVATIONS.

The power applied to the dynamos was measured by a Tatham dynamometer, while the electrical energy was calculated from observations of the potential at the terminals of the machine, the currents in the external circuit and field, and the resistance of the armature. The latter was measured by sending a current from a storage battery through the armature and observing the current in the circuit and fall of potential between the terminals of the machine.

The dynamos were run both on lamps and dead resistance, the value of the latter serving as a rough check on the potential and current.

APPARATUS.

Storage Battery.—This was kindly furnished by Mr. Weston, and was used for all calibrations, measurements of armature resistance, etc. Seventeen cells in series were generally employed; they were placed on boards separated from the floor by porcelain insulators.

Tangent Galvanometer.—This was used for calibrating the current galvanometer. It consisted of a single turn of large sized wire fastened on the edge of a wooden disc which was nailed against a square board frame. The ends of the wire were bent up parallel to each other and fastened by brass connectors to the leads. A correction due to the space between the ends of the turn was applied to the mean radius.

The diameter, about two metres, was measured in different directions, and the mean taken in calculating the constant.

There was a space cut in the middle of the wooden frame, with a shelf for the compass and needle. After the needle was adjusted to the centre and leveled, plumb lines and pointers were arranged so that any warping or change of level could be at once detected.

The value of H was determined by a magnetometer of the coast survey pattern with detached theodolite; it was found to be

.1938

and the constant of the galvanometer;

31.088 ampères.

External Resistances of Dynamos.—The "dead" resistances for the external circuit of the dynamos were made of german silver strips 1¼ inches wide by about .01 inch thick. They were eight in number, each wound on a frame about 3 feet square by 10 feet high, made of four wooden uprights with pieces framed across at the top and bottom. Porcelain insulators were fastened horizontally to the cross pieces and the resistances passed under one of the bottom insulators, over one at the top, to the bottom again, etc. Heavy copper wires were hard soldered to the ends of the strips and taken to the switch board.

The resistances were adjusted by cutting out part of the strip by a short length of german silver with clamps at the ends, which could be shifted to cut out as many of the turns as was desired. The coils were adjusted by means of a calibrated bridge, to 2.400 ohms at 20° C. There was a good air circulation in the room and 50 ampères could be carried by each coil.

In the same room with the german silver resistances were the racks for the incandescent lamps used for "live" resistances.

Switch Board.—Two troughs about 2½ feet long and 1½ inches wide, and 10 inches apart, were cut in a heavy block of wood. Between them were bored two rows of eight holes each, and into these were fitted glass insulators turned upside down to serve as mercury cups. The wood was soaked in boiling paraffine, and melted paraffine poured between the cups and allowed to harden. The distance between the troughs and the middle of the nearest row of cups was three and a half inches; between the two rows,

Digitized by Google

and the cups in each row, three inches. The cups and troughs were filled with mercury, heavy amalgamated copper rods in the latter serving to increase the conductivity. The resistances were brought to opposite cups in the two rows.

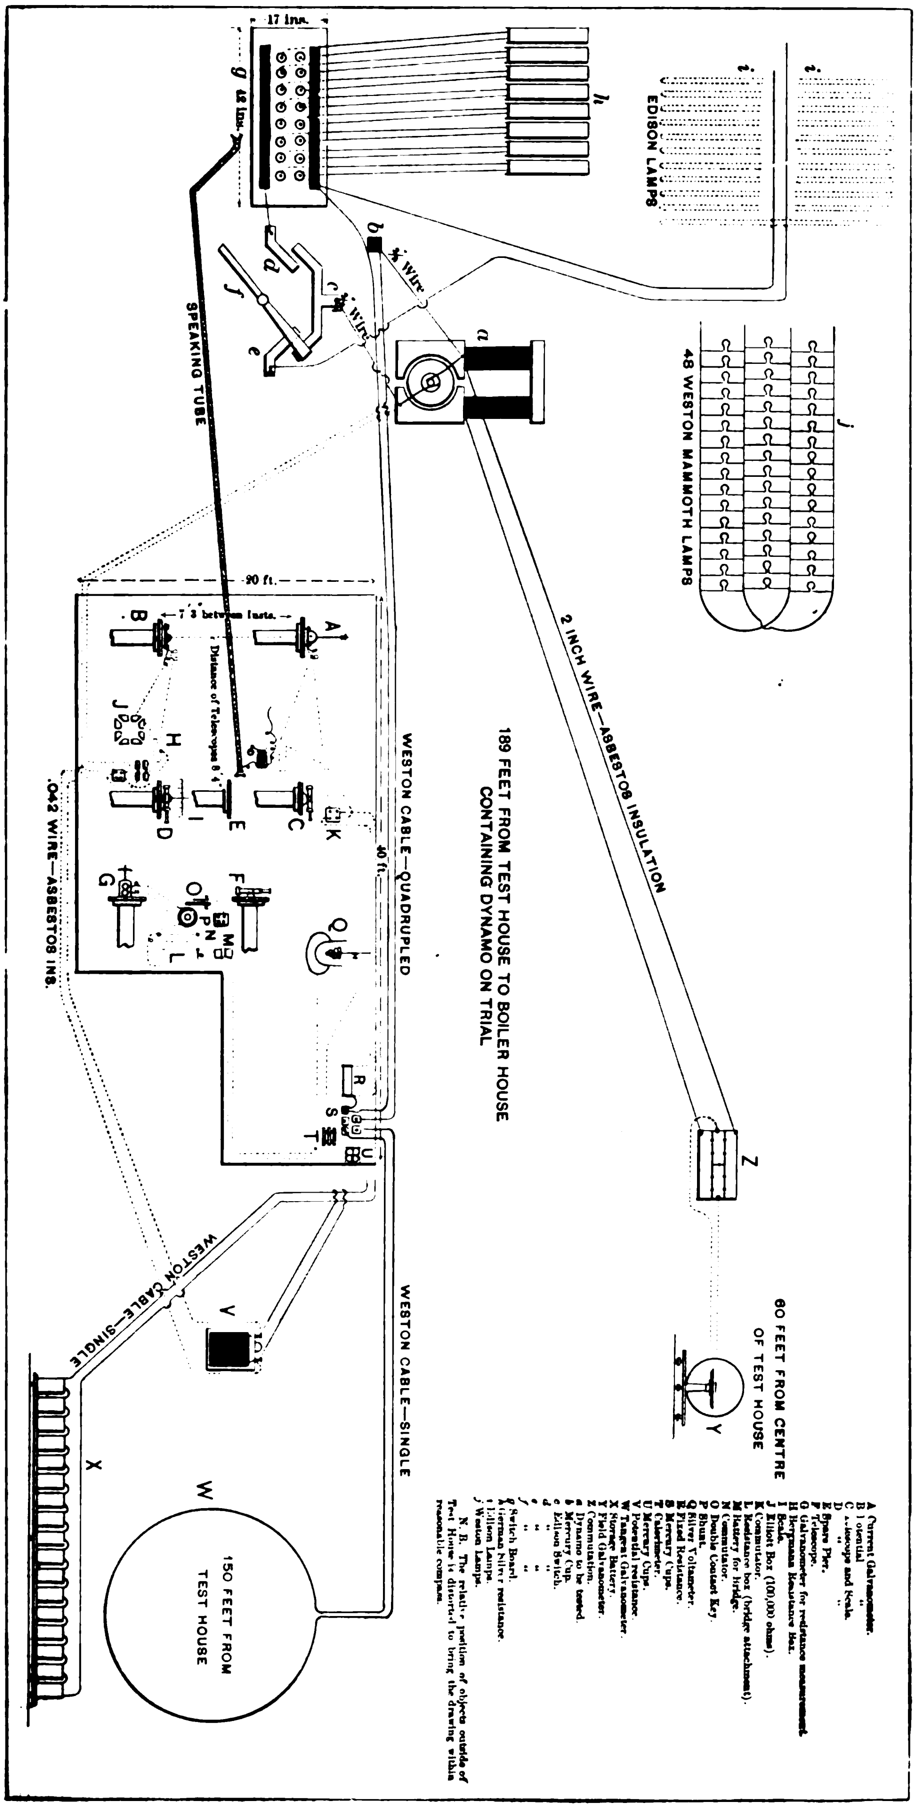

FIGURE 1.—ARRANGEMENT OF TESTING APPARATUS.

The dynamo circuit was from one terminal of the machine to an ordinary Edison switch, by which the current could be made or broken, to one of the troughs; through the resistance to the other trough; to the test house, passing through the fixed resistance for current measurement there; back by the other lead to the dynamo.

Connections at the switch board were made by thick U-shaped copper rods, with a stretch of three and one-half inches. The resistances could be readily arranged in any desired way, with little or no chance of causing accident by making mistakes. The insulation between the troughs and the cups and the troughs themselves was practically perfect.

Field Galvanometer.—The current in the field of the dynamos was measured by a tangent galvanometer of the Helmholtz type, the coils being each a single turn of large sized wire. It was calibrated at the same time as the current galvanometer, being reversed as often as possible, and the same end of the needle read on each side of the zero mark.

Wheatstone Bridge.—For measuring resistances that could not be taken to the Johns Hopkins University, a resistance box, with a bridge attachment by Elliott, of London, was used, with a Thomson astatic mirror galvanometer. The box was standardized, as described below.

Calorimeter.—The calorimeter is shown in figures 2 and 3.

This was used for calibrating both the potential and current galvanometers; it was made of copper, was cylindrical in shape, about eight inches in diameter by ten inches in height, and held about 18 pounds of water.

The cover was screwed to a flange on the cylinder, the joint being water-tight; in it were holes with raised flanges around them, for the terminals of the coil and the thermometer. For stirring, a shaft, working in a bearing on the bottom of the cylinder and passing through the cover, had on it five paddles arranged along its length and at different angles around it, and bent to throw the water past the wire out to the side of the vessel. On reaching the side, a downward motion was given to it by strips of light copper, making an angle of about 30° with the vertical, soldered to the cylinder and projecting inward one and one-fourth inches. On the bottom of the shaft was a propeller blade. Putting saw-dust on the water and turning the shaft slowly showed the circulation to be excellent. Turning the wheel belted to the pulley on the shaft three times per second, raised

Digitized by Google

the temperature of the calorimeter .02° C. in five minutes. In the later experiments it was only turned once per second, so the error from this correction must have been small.

In the first three experiments, copper wire of about 1.3 ohms resistance was used ; in the last two, platinum-silver wire of 1.1 ohms. The coil was held in the cylinder as follows : At equal distances around the cylinder, at the top and bottom, were soldered pieces of copper projecting inward, with clamps at their ends. The wire was wound on glass rods held in a light frame work ; the whole was placed in the cylinder, the rods clamped in place and the framework cut away, leaving a clear space for the stirring arrangement.

The terminals were small copper cups, thoroughly amalgamated and partly filled with mercury. They were surrounded by a rim of ebonite and wedged in their places in the cover.

The calorimeter fitted in a light iron frame, from which it was separated by small blocks of ebonite. The whole

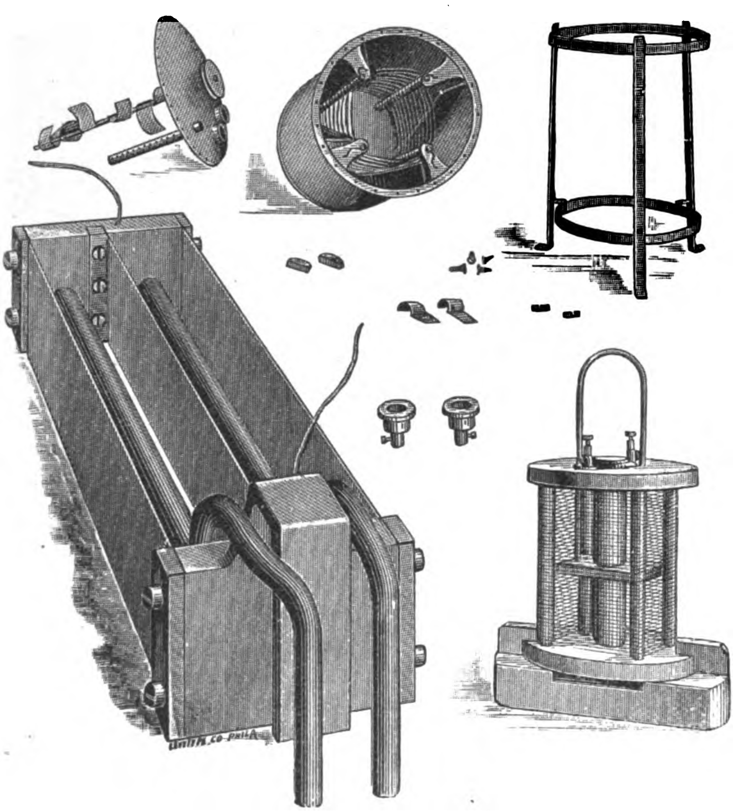

FIG. 2.—Calorimeter, Fixed Resistance and Potential Resistance.

was surrounded by a tin cylinder fitting closely on the shelf to which the frame was fastened, so there was no draught past the cylinder.

Balances.—Two balances were used, one for weighing the calorimeter, the other in voltameter work. The former could weigh up to 30 pounds and was very sensitive. The latter was an excellent analytical balance. Both were by Trœmner, of Philadelphia, and the weights were compared with standards in his possession.

Thermometers.—The thermometers generally used were by Green, of New York. They were divided into degrees and tenths, and were compared at the Johns Hopkins University with one of the standards there, the apparatus used in the comparison being that described by Professor Rowland, in his "Determination of the Mechanical Equivalent of Heat."[1] For the last two calorimeter experiments, a thermometer by Hicks, of London, was used. It was graduated to centimetres and millimetres, and was one of those used by Mr. Leibig, in his work "On the Variation of the Specific Heat of Water."[2]

Potential and Current Galvanometers.—These will be described under measurements of potential and current. They, with the other instruments in the test house, rested on stone slabs cemented on the top of heavy wooden posts, sunk about two and one-half feet in the ground.

MEASUREMENT OF RESISTANCE.

For the standard resistance, a ten B. A. unit coil by Elliott, which had been compared at the Cavendish laboratory, and was used by Professor Rowland in his recent determination of the ohm, was employed. The values of the resistances in terms of this coil were reduced to the Paris ohm, by dividing by

1.0112

The bridge used in the comparisons was built at the University workshops, Cambridge, England. Its fixed (equal) arms were connected by a platinum-silver wire bent in a circle, and their ratio changed by making contact with the galvanometer circuit at different points on the wire. Beside the wire was a scale, and on the arm carrying the galvanometer contact, a vernier reading to tenths of a division. When the fixed coils were each one ohm, a whole division of the scale meant a change of one part in 10,000 of the ratio, while with the galvanometer used, a change of one-tenth of a division, or one part in 100,000 could be detected. The bridge had been calibrated for use in the determination of the ohm. With fixed coils of one ohm, the range of the instrument was about ten per cent., so the resistances to be compared were always approximately equal.

The different coils to be compared were balanced against resistances taken from "comparators," designed by Prof. Rowland. Each of these consists of ten coils of equal resistance wound together on a copper cylinder, the whole being coated with wax or paraffine and put inside a larger cylinder, the space between being filled with feathers. At the top, the cylinders are separated by an annular sheet of hard rubber, around which two circles of ten holes each are bored for the terminals. The ends of each coil are taken to copper blocks screwed firmly beneath opposite holes in the two circles. The tops of the copper blocks are thoroughly amalgamated and the holes partly filled with mercury, connections being made by short U-shaped copper rods.

Three comparators of 10, 100 and 1,000 ohms were used, giving a range of from 1 to 10,000 ohms.

Each coil of the 10-ohm comparator was balanced directly against the 10-ohm standard, then the ten coils in series were balanced against each of the 100-ohm coils, and finally the 100-ohm comparator in series compared with each of the 1,000-ohm coils. In the measurements, the inner cylinders of the comparators were filled with water and the standard immersed in water, the temperatures being noted.

The zero of the bridge scale was taken as the mean of the readings when the resistances being measured were reversed.

In measuring the resistance boxes, they were kept for six or eight hours in a room whose temperature was nearly constant, and then balanced against corresponding resistances taken from the comparators, the temperatures being, of course, noted.

The coil for potential measurement was immersed in turpentine, its temperature recorded, and its resistance measured as above.

The resistances compared at the Johns Hopkins University were the box for current measurements, the coils and bridge for measuring resistance, and the coil for potential measurement.

MEASUREMENT OF POTENTIAL.

The galvanometer used for potential measurements was

1. Proceedings of the American Academy of Arts and Science, 1880.

2. *American Journal of Science*, July, 1883.

Digitized by Google

by Hartmann. It was furnished with a Siemens' bell magnet, closely surrounded by a solid copper block, and dampened very readily, only making two or three swings before coming to rest. The suspension was a silk fibre about fifteen centimetres long. The coils, specially wound over the regular winding of the instrument, had a resistance of about two ohms.

The galvanometer was in a circuit with resistances that were varied from 1,000 to 150,000 ohms, taken from boxes, two of 100,000, one of 10,000 ohms, the former by Elliott and Breguet, the latter by Bergman. All calibrations being made with the (30,000 + 20,000) Elliott coils in the circuit, it was necessary to compare the other resistances with these coils. The arms of the bridge being made equal, the (30,000 + 20,000) and (40,000 + 10,000) Elliott coils were balanced in succession against the 50,000 Breguet, resistances being added to one or the other until there was no deflection of the galvanometer. It was found that

50,000 Breguet = (30,000 + 20,000 + 280) Elliott.
50,000 Breguet = (40,000 + 10,000 + 250) Elliott.

The (30,000 + 20,000) ohms Elliott was also measured in terms of the bridge coils, and the value found, 49,960, was so nearly correct that in getting the ratios of the 1,000 and 2,000 ohms Bergman—used in measuring armature resistance—to the (30,000 + 20,000) coils, it was assumed that their values in terms of the bridge coils were the same as if measured in terms of the (30,000 + 20,000) ohms.

The deflections were read by a telescope and scale, the latter by Brown and Sharpe, graduated to centimetres and millimetres. The distance from the telescope to the mirror was two and one-half metres.

Calibrations.—The galvanometer was calibrated, both by measuring a current passing through a standard resistance at whose terminal the leads of the instrument were connected; and by the difference of potential at the terminals of a calorimeter. The constant was also checked with that of the current galvanometer, after each test, by measuring the current through the german-silver strips used for the external circuit of the dynamos, and the potential at their extremities.

During the tests, 40 calibrations were made; 36 with the silver voltameter and standard coil, and four with the calorimeter. The constants determined by the calorimeter agreed so closely with the measurements by the voltameter, and the labor both of observation and calculation in the former was so much greater than in the latter, that it was thought unnecessary to make the observation any oftener.

Voltameter Calibrations.—The current used varied from one to one and one-half ampères, giving a difference of potential at the terminals of the standard coils of from 20 to 30 volts. The coil shown in figure 1 was of No. 22 german-silver wire, wound on glass rods fixed in a wooden framework. The turns were kept apart by silk cord wound on the rods. The whole was immersed in a high grade oil (300° fire test) kindly furnished by the Standard Oil Company. The oil was constantly stirred while the current was passing. The measurement of the resistance has been described. Its value was

21.161 ohms, at 14° C.

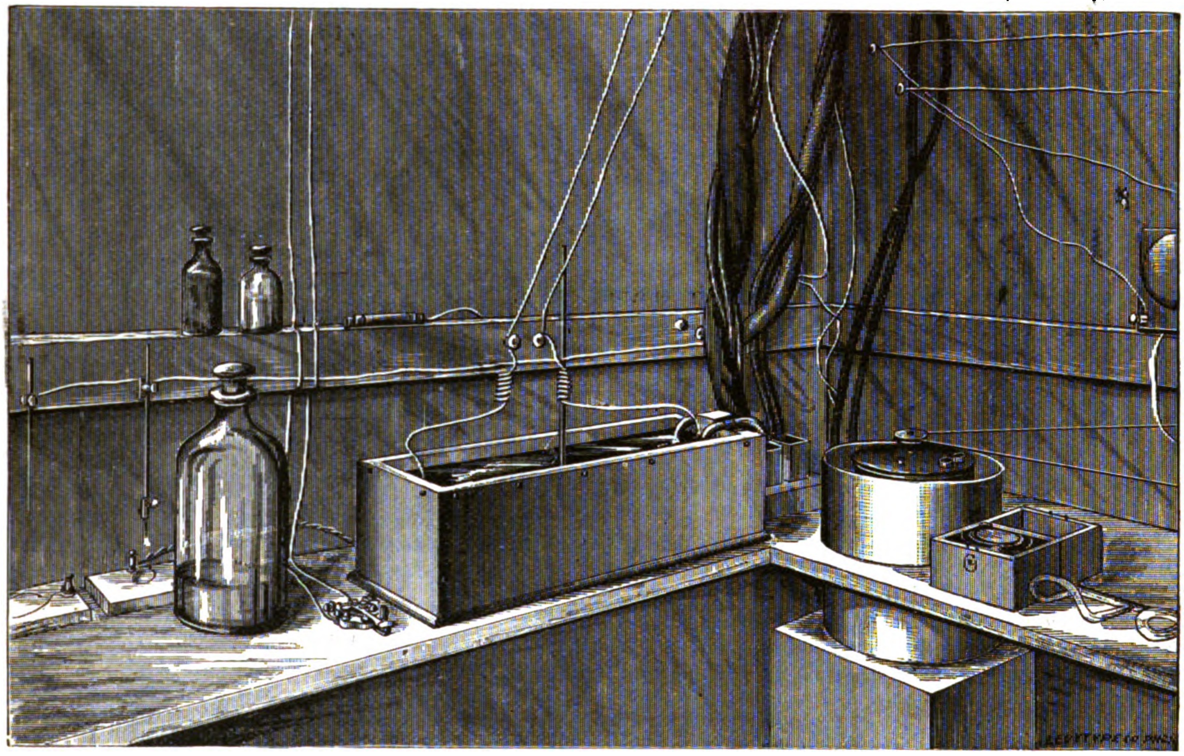

FIGURE 3.—Test Room with Instruments in Position.

For measuring the currents, a silver voltameter was used, the anode being a spiral of silver wire wrapped in filter paper, the cathode a platinum crucible filled with a 40 per cent. solution of silver nitrate. The calibrations took from 10 to 20 minutes, the deposit ranging from .9 gram to 2. grams. The times were noted by a chronometer whose rate, + 1 second per day, was neglected.

When the experiment was finished, the solution was poured out of the crucible; the deposit first washed with distilled water, then allowed to soak from one-half hour to 12 hours, then washed again until there was no precipitate with a solution of sodium chloride, and finally slowly dried and then weighed.

A double reading of the galvanometer was taken each minute, and the constant calculated from the mean reading for the time of observation. The constant is given by

$$k_{50} = \frac{C\,R\,(1 + M_c\,(t_c - 14^\circ))}{2d} \left\{ 1 - M_b\,(t_b - 25^\circ) \right\}$$

where

k_{50} = constant for (30,000 + 20,000) ohms;
R = resistance of standard coil at 14°;
t_c = temperature of standard coil;

M_c temperature coefficient of standard-coil;
M_b = temperature coefficient of box;
t_b = temperature of box;
$2d$ = double deflection of galvanometer;
25° being taken as the standard temperature of the box.

When other resistances were used in the circuit, the constant was multiplied by their ratio to the (30,000 + 20,000) ohms.

Calorimeter Calibrations.—The calorimeter has been described. In making the observations, the time the mercury crossed each half degree or centimetre of the thermometer was taken as the mean of the times of crossing the tenths before and after the division, and the division itself. In calculating the water equivalent of the calorimeter, the weight of the shaft was multiplied by the specific heat of steel; that of the cylinder by the specific heat of copper, and the weight of the glass and wire by their specific heat. For steel, the value of the specific heat was assumed to be

.1110

and that of copper

.0940

The principal correction to be applied is due to radiation. The other corrections are for rise of temperature from stirring, for the part of the thermometer stem in the air, and a small one for weighing in air.

The coefficient of radiation was determined by noting the rate of cooling, the calorimeter being slowly stirred. Experiments gave

Difference between air and calorimeter,	10° C.	coefficient, .00154
" " " " "	5° C.	.00150
" " " " "	0° C.	.00149

Before the experiments, and for the determination of the radiation, the cylinder was carefully polished.

The correction for stirring was determined by bringing the calorimeter to exactly the temperature of the air, and then turning the wheel belted to the pulley on the shaft three times per second. The rise of temperature was .02° in five minutes. For the smaller velocity used in the later experiments, the heating was assumed to vary as the cube of the velocity.

The correction for the temperature of the stem was taken from

$$c = .000156\, n\, (t - t'')$$

The following is one of the calibrations:

In making the calculations, Rowland's value of the mechanical equivalent was taken, because the thermometers used in the above experiment were compared directly with those employed by Prof. Rowland, and thus errors in thermometry were to a large extent eliminated. Probably the greatest source of error in the calorimeter experiments was the superheating of the wire in the water. Using platinum-iridium wire varnished, with a smaller current than was generally employed in these experiments, Mr. L. B. Fletcher calculates[8] that the superheating is about 2° C. But in the measurements described above the wire was bare and the flow of water past it very much faster than in Mr. Fletcher's work. In the last two experiments a rise of 2° C. would cause an error of less than one-tenth per cent., so it is probable that they are not much affected by this source of error.

It is also possible that there was conduction through the water. The calorimeter was carefully cleaned before each experiment and distilled water used. If such an effect existed, it would be in an opposite direction from the superheating.

The usual range of temperature was 10° C.; in the experiment given it was a little over 6°.

Besides the regular calibrations, the constant was calculated after each test, from the potential at the extremities of the german silver "dead resistance," the current being measured by the current galvanometer, and the resistance measured by the bridge. The following partial list of calibrations excludes measurements made in this way. It

For the Edison Nos. 5 and 10 dynamos, the potential galvanometer was in the same position as when used for the duration test of lamps, in a room at some distance from the test house. The constant as determined during the tests of these machines agreed closely with that used in the duration tests, which had but just ended. But when the instrument was removed to the test house, the constant began to vary, changing greatly from day to day, with sometimes a sharp change during the day. The Weston No. 7 M dynamo was tested on full load with the constant in this unsatisfactory state, and between the second and third tests there was a change of over one per cent. Although the number of calibrations made these measurements perfectly trustworthy, yet the labor and anxiety were both too great to be repeated with each test.

So before the machine was run on the partial loads, the galvanometer was taken to pieces, the coils rewound and soaked in paraffine, and the stand of the tube carrying the suspension more firmly secured. A beam, which pressed against the wooden pier, was also cut away. After this, the constant did not vary, the calibrations rarely differing more than one-tenth per cent. from the constant used.

MEASUREMENT OF CURRENT.

The currents were measured by observing the ratio of the potentials at the ends of a fixed resistance when a known current and the current to be measured were passing respectively. To do this, the terminals of a circuit containing a galvanometer and a resistance box were permanently fastened to the extremities of the fixed resistance. A current was sent through the latter, and the resistance of the box adjusted until the proper deflection of the galvanometer was obtained; the current was measured by the voltameter, tangent galvanometer, or calorimeter, and the deflection and resistance was observed. When any other current was to be measured, the box was changed until the deflection was about the same as before, and both the deflection and resistance noted. The thermometers used in getting the temperatures of the different parts of the circuit were those by Green, already described.

The notation and formulæ used are as follows:

Let C' be the current used in calibration ;
r' be the resistance used in calibration ;
d' be the deflection used in calibration ;
t'_s be the temperature of fixed resistance at calibration ;
t'_b be the temperature of resistance box at calibration ;
t'_g be the temperature of galvanometer at calibration ;
C'' be the current to be measured ;
r'' be the corresponding resistance ;
d'' be the corresponding deflection ;
t''_s be the corresponding temperature of fixed resistance ;
t''_b be the corresponding temperature of the box ;
t''_g be the corresponding temperature of galvanometer ;
t_o be the standard temperature = 25° C.;
u_g be the temperature coefficient for galvanometer circuit ;
u_s be the temperature coefficient for fixed resistance and box ;
G be the galvanometer resistance ;
k be the constant at 25° C.

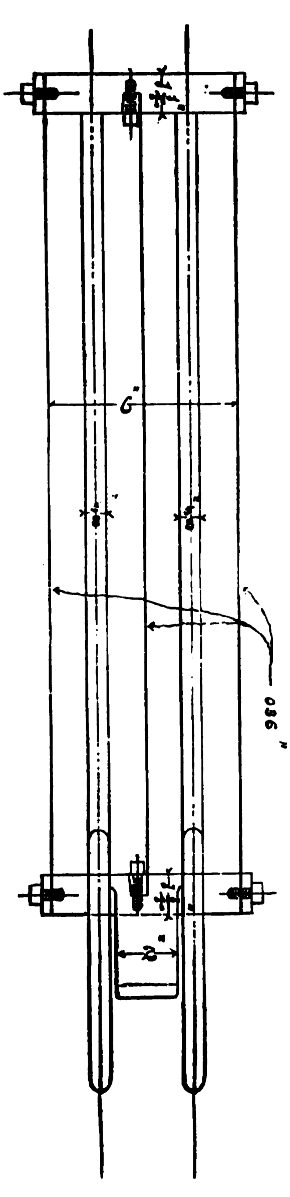

FIGURE 4.—Plan.

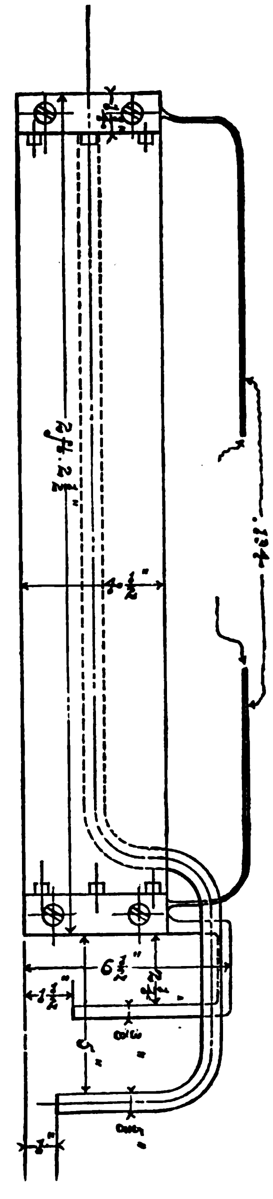

FIGURE 5.—Side elevation.

Then

$$k = \frac{C'}{2d'} \frac{1 + u_s(t'_s - t_o)}{[G\{1 + u_g(t'_g - t_o)\} + r'\{1 + u_s(t'_b - t_o\}]}$$

$$C'' = k\, 2d'' \left[1 - u_s(t''_s - t_o)\right] \left[G(1 + u_g(t''_g - t_o)) + r''(1 + u_s(t''_b - t_o)\right]$$

Calculations were facilitated by making tables of

$$G\{1 + u_g(t_g - t_o)\}$$

for the different temperatures, of

$$r\{1 + u_s(t_b - t_o)\}$$

for the different resistances that were to be used, and of

$$1 - u_s(t_s - t_o)$$

for the different temperatures of the fixed resistance.

Galvanometer.—A mirror galvanometer, by Edelmann, of Munich, was used. It was furnished with a ring magnet damped by surrounding copper blocks. The suspension, originally about two feet long, was shortened to about seven or eight inches by a copper rod passing inside the glass suspension tube; there was no trouble from vibrations. The coils were movable on graduated bars, but for the tests they were clamped and their position never changed. The resistance of the coils, with the fixed resistance and the leads to it, was

.3973 ohms, at 25°.

This was taken as G in the formulæ, and the temperature coefficient for copper used; the value of the german silver fixed resistance being only about .0004 ohms, and the rest of the circuit being copper. The galvanometer was read with a mirror and scale, the latter being of porcelain, graduated to centimetres and millimetres. The distance from the galvanometer was 2.5 metres.

Resistance Box.—The resistance box, by Hartmann, being open at both ends and having no paraffine on the coils, was very well fitted for its work. Its measurement has been described.

Fixed Resistance.—The details of the fixed resistance are shown in figures 4, 5 and 6, which are respectively, a plan, side elevation, and end view. It is also shown in perspective in figures 2 and 3. It consisted of three strips of german silver, 4½ inches broad by ·036 inches thick, the ends hard-soldered into heavy copper blocks.

One of the blocks had a terminal piece cast on it that was bent to clear the edge of the tank in which the resistance was placed, and dipped into a mercury cup, to which one of the main leads was brought. From the other block, two copper rods passing between the strips, were bent over the edge of the tank and dipped with the other main lead into another mercury cup. The terminals of the galvanometer circuit were soldered into the copper blocks and remained permanent during the tests. The whole was put in a rectangular tank filled with the same kind of oil as was used for the potential resistance.

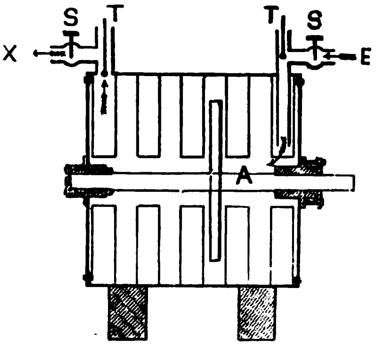

FIGURE 6.—End view.

Calibrations.—Calibrations were made by sending a current through the fixed resistance, measuring it, observing the deflection of the galvanometer and the resistance in its circuit, and noting the temperatures. The calibrations usually lasted ten minutes. The constant was calculated by the formula already given.

Three methods of measuring current were used; the silver voltameter, tangent galvanometer and calorimeter.

For the voltameter calibrations, a large platinum dish was used as cathode, a flattened spiral of silver wire wrapped with filter paper as anode, while a forty to fifty per cent. solution of silver nitrate was employed. With this strength of solution and with the usual current, about four ampères, the deposit was very regular and beautiful. It was treated as described under potential measurements. The resistance in the circuit was about 10 ohms.

The tangent galvanometer has been already described. Two observers read both ends of the needle on each side of the zero mark. The current was reversed every minute; it varied from 20 to 30 ampères.

The method of using the calorimeter has been described. The observations give $C^2 R$, and R being measured by the bridge, C may be found, with the advantage that errors of observation are halved in the value of C.

Altogether, there were five calibrations by the tangent, nine by the voltameter and five by the calorimeter. The following are the values obtained:

.024510	by voltameter.
.024510	by voltameter.
.024440	by tangent galvanometer.
.024550	by tangent galvanometer.
.024510	by voltameter.
.024480	by voltameter.
.024590	by tangent.
	by calorimeter.
.02455	by tangent.
.02455	by voltameter.
.024481	by calorimeter.
.024477	by calorimeter.
.024520	by tangent.
.024500	by voltameter.
.024516	by voltameter.
.02453	by calorimeter.
.024495	by voltameter.
.024494	by voltameter.
.02450	by calorimeter.

This principle of measuring current has been used before, notably at the Vienna and Munich exhibitions, but as employed in the following tests the method differs from that previously used in an important particular, *i. e.*, the construction of the fixed resistance. The substitution in the fixed resistance of german-silver strips in oil instead of the copper bars in air formerly employed, increased greatly both the range and accuracy of the method.

As the method has not been commonly used, and is possibly not very generally understood, a brief discussion of the sources of error and their probable value in these tests will be given.

The possible sources of error are:
(1.) In observing the deflections;
(2.) In the constant;
(3.) In the temperature correction for fixed resistance;
(4.) In the temperature correction for resistance box;
(5.) In the temperature correction for galvanometer;
(6.) In the values of the coils in the box;
(7.) In the resistance of the galvanometer coils;
(8.) In assuming the currents proportional to $2d$.

(1.) Error in observing the deflections.

This error would enter directly in the result. The scale could be read with considerable accuracy to tenths of millimetres; the double deflections were usually between twenty and thirty centimetres. The currents measured were quite steady, but even if they varied, the excellent damping of the galvanometer would allow the readings to be taken with a good deal of precision.

(2.) Errors in the constant.

On looking at the table of constants, it will be seen that the results obtained with different resistances in the galvanometer circuit, different currents, temperatures and deflections, and by entirely independent methods of measuring currents, agree so closely that their mean must be very near the true constant. Two of them, exceptional ones, differ from the mean by one-third per cent., a few more by one-sixth per cent., but the greater number are within one-tenth per cent. of the constant used. Double weight was given the voltameter calibration, as involving less possibility of error than the other methods; with two exceptions, they are within one-fifteenth per cent. of the mean. Any error would enter directly.

(3.) Errors in the temperature correction of the fixed resistance.

The uncertainty due to the temperature correction of the fixed resistance must have been inappreciable. Its temperature coefficient was small, about one-tenth that of copper, while its temperature, considering the large surface of very thin metal exposed to the liquid, must have been quite accurately known. For the heavier currents, the oil was con-

stantly stirred. With about 400 ampères in the circuit, the thermometer registered .1° C. more when held against the strip than when in the body of the liquid; while the oil rose 1.5° during the test. To further decrease the possibility of error, the oil was kept within at the most 5° or 6° of the usual temperature of calibration by cooling it when necessary between the tests. An error would enter directly in the results.

(4.) Errors in the temperature correction of the resistance box.

Both ends of the box were open to the air and the coils were not coated with paraffine. The bulb of the thermometer lay against or very near the coil in use. The currents could cause no appreciable heating and the temperature of the room changed slowly.

The temperature coefficient was taken as

$$.0004,$$

and calibrations made at different temperatures showed that this was not much in error. Errors would enter almost directly in the result.

(5.) Errors in the temperature correction of the galvanometer coils.

The temperature of the galvanometer coils was given by a thermometer hung near them. With the smallest resistance used, any error in this correction would only enter as one twenty-fifth in the result.

(6.) Errors in the values of the coils in the resistance box.

The measurement of the resistance box has been described. The values were probably correct within one part in 2,000 or 3,000. Any error would enter directly in the result.

(7.) Errors in the resistance of the galvanometer circuit.

The resistance of the galvanometer and its circuit was measured by the standardized bridge. The error was probably small and entered at the most as one twenty-fifth in the result.

(8.) Error in assuming the currents proportional to $2d$.

This error is slight and was to a large extent eliminated by making the calibration on about the same part of the scale as the measurements.

The only errors then that would be appreciable are in the deflections, the constant, the temperature correction of the box, and the values of the resistance coils. The last of these could hardly have been over one-twentieth per cent.; the temperature correction of the box was probably within one-tenth per cent.

This method has several advantages. The range is very great (with the apparatus described currents of from two or three ampères to 400 could be measured with about the same accuracy) while the errors are not multiplied in the result and are of such a nature that with proper precautions many of them can be almost entirely eliminated, and the rest made very small.

Although in measurements of both potential and current any change in H would directly affect the results, yet as certainly two and usually more voltameter calibrations were made for each day of the tests, and the constants were checked after each measurement, it is not probable that any important error arose from this cause.

It is also interesting to note that the magnetometer records that showed such irregularities during the life test of lamps just finished, were remarkably uniform during the dynamo tests.

(*To be continued.*)

EXPERIENCE WITH SUBTERRANEAN LINES.[1]

BY DAVID BROOKS.

With this memorandum I leave with you, numbers of the Journal of the Society of Electricians and Telegraph Engineers. These papers give a very complete history of underground electrical work in England and France. You will find there have been very many attempts to use pitch, asphalt, bitumen, coal tar, or whatever name you please to give it. They are essentially the same. Many of these experiments were made more than twenty years since, and Mr. Cully in the eighth edition (just issued) of his work, gives the substance of all these trials in the following words:

"It has often been proposed to insulate underground wires with bitumen but so far without success."

When I appeared before this committee at a previous meeting I referred to the many attempts to insulate wires drawn into lead pipe. These wires have been wound with cotton and the pipe filled with melted rosin, asphaltum, bees-wax or paraffine.

I take the credit of ascertaining the prime cause of the failures. Page 34 of numbers 13 and 14, vol. 5, of these journals give an account of an experiment with paraffined wires in lead pipes made by the post-office authorities in London in 1875.

A Swiss firm secured a patent for molding lead in a cold or unmelted state over these paraffine cables and gave samples for trial to nearly all European governments. The tests were unsatisfactory as moisture would go through the pores of the lead. They next wound an insulating covering, consisting of jute soaked with tar, over the pipe and then molded a second covering of lead over the whole with better results. I show you a specimen, or rather a cut, of this device to protect an electric light conductor. See figure 1.

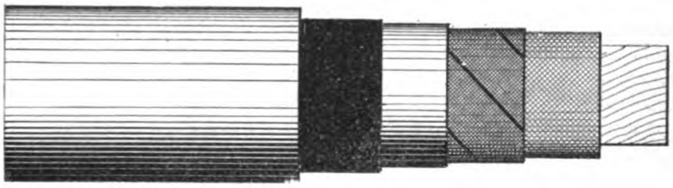

FIGURE 1.

Another method of remedying this difficulty is to lay the lead pipes in a trough, and embed them in melted pitch. The objection to the first method, that is, using two pipes with an insulating medium between them, is that it very materially increases the cost. The objection to the second method is that it is next to impossible to remedy a defect in the conductors caused by atmospheric electricity or high tension currents. The whole system would have to be dug up.

You will find by reading the article by Mr. Fleetwood, the engineer in charge of the London system, that one of their greatest troubles is the effect of atmospheric electricity, although their conductors are carefully provided with lightning arresters. These do not always protect the insulation.

The cables crossing the North river often receive injury from this cause. Atmospheric discharges are more frequent in New York and vicinity than in London, but a cable in the North river can easily be underrun, the hole punctured by lightning found and sealed up, and the cable dropped again to the river bottom. But a lead cable covered with pitch and buried in the ground, when injured by lightning is exceedingly difficult or almost impossible to repair.

When a difficulty of this nature occurs to one of the underground wires in London, they let it remain and connect in its place a "spare" wire, the iron pipe in the first place having twice as many wires therein as their present necessities require. When a sufficient number of these wires become defective the whole of the conductors are pulled out and another group inserted. It was the original intention, when one wire failed, to pull it out and replace it with a good one but it was found that this operation often injured the good wires by abrasion, and now, instead of pulling out one, they pull out the whole cable and sub-

1. Read before the New York Commission on Electrical Subways October 13 1885.

Digitized by Google

stitute a new group. I have never heard of any of the conductors that I laid in London being injured by lightning although all of them are connected to overhead wires at Clapham Junction, but if they were thus injured the cable is much more easily drawn out of the pipe, since the latter is scoured smooth inside and lubricated with oil.[2] I see it often stated that the underground railways in London afford great facilities for carrying out their underground systems. This is a mistake. Page 41, numbers 13 and 14, vol. 5, of the Journal gives Mr. Fleetwood's reasons why these underground railways or passages have not been used.

Paris sewers are supposed to give great advantages for the underground system, but if you will read Mr. Aylmer's report, it will be seen that it is much more expensive than the London system. For telephone purposes, the authorities charge the telephone company 15 per cent. of their gross receipts. The sewers are a wonderful piece of masonry.

Paris is situated on the two slopes of the river Seine; the sewers were made by tunneling from the shores of the river under the hills and are at a much greater depth beneath the street surface than is generally supposed. In the centre of the sewer, there is a canal with a sidewalk on each side wide enough for three men to walk abreast, but in another sense unlike a canal and more like a mill race because the water flows with great rapidity. This channel is supplied with water at its greatest elevation, and this water runs with such force and in such quantity that all the sewage of the city is quickly carried into the river. I had the pleasure of walking four miles through the sewers and saw no still or stagnant water. The stream in its rapid course keeps the atmosphere comparatively pure.

CONDUITS.

There has been a great deal said about having an open space or chamber under the streets where everybody could go and place their wires. The lowest estimate of the advocates of the cost of such a subterranean chamber is greater than that of a thousand wires already laid by the system I recommend. Bear in mind this is the price of a conduit without a wire or conductor in it. There are over a hundred diversified interests in the overhead wires in New York, and some of these interests are antagonistic. (See court proceedings often reported in the papers —accounts of cutting and seizing each others wires.)

Not long since these proceedings were carried on to such an extent by the agents of the different companies in the state of New Jersey and so at variance with the laws of that commonwealth that they got themselves into jail. Imagine themselves settling their differences as to right of way in an underground tunnel in New York city!

A conduit unless placed below the gas mains is a dangerous thing. Gas leaks into it and when mixed with air, one part gas to about 14 of air, is explosive. There is a short conduit in Philadelphia laid only a short time since but sufficiently long to have startled the business portion of Chestnut street with three grand explosions, throwing heavy cast iron man-hole covers high into the air.

No. 12, volume 4, page 403, states how gas collected in the pipes containing the wires in London causes explosions and injury to the conductors.

It has been proposed to use creosoted wood conduits. These things have had their trial in London also; they soon decay, the street caves in and requires repairing. It is only the cheapest and most perishable kind of wood that will take creosote; such as is known in this country by the name of pine or hemlock. When green, half of their weight consists of sap or water. After being treated they will not last underground nearly as long as oak, chestnut or the more closely grained woods. The earth under the pavement in New York is sand or gravel, and wood, or iron, or even lead is soon affected by the gases working through this loose material; besides the ammoniacal salts and animal impurities working below the surface tend to bring on rapid disintegration and decay. We counteract these influences as much as possible by inclosing the wrought iron tubes in solid pitch. The wooden box is used merely to keep the pitch in place while hot and in a liquid state.

India-rubber is not used in any of the European countries for insulating wires underground or under water. As an insulating material for that purpose, its life is short. All the nationalities have tried it. Several large establishments were erected at great expense in London for the purpose of insulating wires and cables with that material, but they failed in so short a time that these enterprises were abandoned,—notably Hooper's works, costing millions of dollars, which were sold under the hammer, including the great iron steamer the "Hooper" of 8000 tons burden built expressly for laying ocean cables. But for in-door use it answers every purpose, and is so used almost exclusively in Europe. If in this country it had been used instead of cotton covered wires, many disastrous fires would have been prevented, especially since lighting by electricity came into use. Gutta-percha insulation is now almost entirely used for underground and under water purposes.

Twenty years ago the price was not over 50 cts. per lb. now it is worth from three to four dollars per lb. owing to the diminishing supply; and the prospect is that it will become still dearer as no other material yet discovered answers for ocean cables.

The early attempts to use gutta-percha for underground purposes were unsuccessful as you will see by reading these volumes.

The patent for my system was granted on the 17th day of December, 1878, and expires on the 17th day of December, 1895, a little over ten years hence, and then the system becomes public property.

The wires that I have laid during the past six years, have been attended with less failure, than any equal number and length of gutta-percha insulated wires, wherever they may have been laid. I make this statement without fear of contradiction.

A letter from W. H. Preece, government electrician, under date of Oct. 2, 1885, speaking of my London lines says "Your wires are working very well."

The London specimen consists of 40 conductors in an inch and a quarter diameter pipe four miles long, making 160 miles of conductors laid 1880.

A letter from the department of posts and telegraphs, Brussels, M. Bertin, engineer, March 1st, says:

"The conduit which you laid in Bruges, in 1879, has since been subjected to numerous tests which have demonstrated that the high insulating resistances of all the wires had not perceptibly varied since the work was done. The good results which have been obtained have induced the Belgian government to look into the advisability of laying a conduit with a larger number of wires, in Brussels."

I enclose a cut showing the actual space of 420 wires underground in Spring street and now in use by the telephone company. I may also mention an interesting fact showing another advantage of my system. Since we laid our tubes in Philadelphia, about two feet below the surface, the line of these tubes has been crossed by traction or cable railways. A wrought iron tube is easily sprung out of line and by digging our trench a little deeper on each side of the crossing, the tube was sprung downward so as to allow the conduit of the traction company to pass over it without injury to the pipe or the wires contained therein.

2. Many of the defects in the insulation of underground conductors come on gradually, and are developed into total failure of insulation by the battery current employed to operate the conductor whenever a solid substance is used for insulation. The battery current does not produce this effect in oil, as the oil is continually moving, expanding and contracting by changes of temperature, and thereby does not permit the current to centre upon any particular spot. In this respect the cable or system resembles a horizontal thermometer. All the interruptions that we have had from lightning or dynamo currents have taken place in the insulation outside of the iron pipes, generally where india-rubber or gutta-percha was used for connecting with overhead wires.

Digitized by Google

Our tube was successfully lowered three and a half feet without any expense to us, but if it had been an electrical conduit of cast iron or masonry, this springing out of line could not have been accomplished.

New York, Oct. 13, 1885.

RESISTANCE OF COPPER WIRE.

BY CARL HERING.

In most text books on electricity, and in many periodicals, values are given for the resistance, or the conductivity, of copper wire, but owing to the difference in the units used, and to the fact that the resistance varies with the temperature, these values are often very unreliable unless the units used and the temperature, are stated in each case. Even if they are stated, the reductions necessary are often so complicated that it is very troublesome to use these values. If they are reduced to the same units, there is frequently a discrepancy found, so that the practical engineer is often in doubt, not only which value to use, but also to what extent he can depend upon it.

To enable the engineer to compare these values better, and in order to get a fair mean value, the writer has collected, in the last few years, a large number of different values given by various authorities, and has reduced them all to the same units in the following table, thus enabling a fair comparison and selection to be made.

The value to which they have all been reduced is what might be called the *specific resistance*, that is *the resistance in legal ohms, of a wire of one square millimetre cross section, and one metre length, at the temperature 0° Centigrade.* Calling this value θ, the formulæ for using it with other units, such as feet and inches, may readily be deduced and can be reduced to such forms as to facilitate calculations very much.

There is also given in the table, the conductivity of the wire calculated from the specific resistance; it expresses the number of times that the copper conducts better than mercury, or in other words, it is the ratio of the conductivity of copper to that of mercury.

In many of the statements from which these values were calculated, the data given was incomplete, so that the writer had to assume certain factors as being most probably the ones understood. In all cases the original data is given, enabling any one to make the calculations, in case the factors assumed are not the correct ones.

In reducing them all to 0° temperature, the following formula was used.

$$R_0 = R_t - R_t\ t^\circ\ 0.0037$$

t° being in centigrade degrees. The constant 0.0037 was taken as a fair mean of a large number of independent statements. It is evident, however, that if a slightly different value is taken for this constant, it will not affect the result very much, as it does not enter as a direct factor.

The factors used in the reductions are as follows:

1 legal ohm = 1.0112 B. A. units.

1 B. A. unit = .9889 legal ohms.

1 legal ohm = 1.06 Siemens units.

1 B. A. unit = 1.0483 Siemens units.

1 ohm as used in Germany = 1.0615 Siemens units.

The first and second values are those given by the secretary of the British Association, on their standard resistances.

It will be noticed that the values coming from the same authority, but compiled from different sources are not alike. This may be due to the fact that they were incorrectly stated in the source from which they were taken by the writer, but it is more probable that they are values obtained from different experiments at different times.

In many cases values are given for pure copper, while in practice commercial copper is always used, the resistance of which is always greater. Several values for commercial copper are given and show what allowances may be made in practice.

The numbers in the first column refer to the paragraphs below, in which the authority and any other remarks are given.

TABLE.

θ = resistance in legal ohms of 1 metre of copper wire, with 1 square m. m. cross section at 0° C.

K = conductivity at 0° C. as compared with mercury at 0° C.

No.	θ	K	Remarks.	No.	θ	K	Remarks.

1. Matthiessen. Resistance of one metre of annealed copper wire of 1 m. m. diameter, at 0° C., is 0.02057 ohms. Hard wire, 0.02104 ohms. From Uppenborn's Kalender. In the first two values the ohm is assumed equal to 1.0615 Siemens units, as that is used throughout the book. In the second two the B. A. unit is taken, it being most probably the one understood.

2. Matthiessen. One mile of pure copper wire $\frac{1}{16}$th inch diameter, at 15.5° C., has 13.59 ohms. The ohm is assumed to be the B. A. unit. From the report of the British Association Committee on Electrical Standards, 1873. This value is employed in the table calculated by Mr. Prescott and published in the ELECTRICIAN AND ELECTRICAL ENGINEER, June, 1885.

3. Matthiessen. Pure copper as compared with mercury: soft 0.0162 Siemens units, hard 0.0166 Siemens units. This, no doubt, means at 0° C.

4. Matthiessen. One metre of pure copper wire of one gram weight, at 0° C., has 0.1469 ohms, sp. gr. 8.95. The ohm is assumed to be the B. A. unit. Another value given is the resistance in absolute units, equal to 1642. These values are quoted by Maxwell and Kohlrausch.

5. Kohlrausch. Pure, soft copper has a conductivity at 18° C. equal to 54 approximately, as compared with mercury at 0° C. The ohm is given as 1.06 Siemens units.

6. Pure copper wire, per mile at 60° F., has $\frac{54892}{d^2}$ ohms. The ohm is assumed to be the B. A. unit. d is, no doubt, the diameter expressed in mils or thousandths of an inch.

7. One metre of soft copper wire of one square mm. cross section at 0° C. has 0.01526 ohms. Hard copper 0.01563 ohms. From Uppenborn's Kalender. The ohm is taken equal to 1.0615 Siemens units. Pure copper is no doubt meant.

8. Taken from Sidney B. Paine's table, published in many price catalogues. 1000 feet of No. 16 pure copper wire at 75° F. with a diameter of 0.050820 inches, has a resistance of 4.179 ohms. The ohm is assumed to be the B. A. unit.

9. Taken from a table published in the London *Electrical Review*, Nov. 3, 1883. One metre of No. 16 pure, soft drawn copper wire with a diameter of 0.064 inches at a temperature of 15° C. has a resistance of 0.00824 ohms. The ohm is assumed to be the B. A. unit. The same author states that the best wire used in practice has a conductivity of 98 per cent. of this value; while ordinary good wire has only 95 per cent. Both these values are given.

10. Commercial copper wire, one metre long, and one square mm. cross section at 15° C. has 0.0166 ohms. Uppenborn's Kalender. The ohm is assumed to be equal to 1.0615 Siemens' units.

Digitized by Google

11. Quoted as being used in the Siemens factory. One ohm is equal to 48.5 metres of copper wire of one mm. diameter, at 0° C. The same author gives the ohm equal to 1.0493 Siemens units. This value was used in the reduction. Commercial copper is assumed.

12. From London *Electrician.* 100 yards of pure copper wire of d inches in diameter, has a resistance of $\frac{0.003118}{d^2}$ ohms. 98 per cent. copper has $\frac{0.003185}{d^2}$ ohms. 90 per cent. has $\frac{0.003478}{d^2}$ ohms. The ohm is assumed to be the B. A. unit. The values are assumed to be at the ordinary temperature of 20° C.

13. From London *Electrician.* 1000 feet of pure copper wire with a diameter of 0.12849 has 0.6259 ohms. The diameter is assumed to be in inches, and the temperature to be about 20° C. The ohm is assumed to be the B. A. unit.

14. Hesse, one of the largest manufacturers of copper wire in Germany, guarantees his wire to have a conductivity of from 57 to 60. This is said to be above the usual values.

15. One metre of soft copper wire of one sq. mm. cross section, has 0.01526 ohms. Hard copper, 0.01563 ohms. The ohm is assumed to be equal to 1.0615 Siemens units. The wire is assumed to be pure and at 0° C.

16. Three different values determined by Weber in Munich, of copper from different sources to show the variation. The last one is from Hesse, Germany. They are quoted as specific resistances.

Representing the specific resistance as given and defined in this table, by θ, the following formulæ will enable one to calculate either the resistance in legal ohms, the length, or the size of a copper wire, any two of the factors being given.

Let
- R = the resistance in legal ohms.
- L = the length in feet.
- l = the length in metres.
- D = the diameter in inches.
- d = " " millimetres.
- A = the cross section in square inches.
- a = " " " square millimetres.

The temperature is assumed to be 0° C. unless otherwise stated.

$$R = .0004724 \frac{L\,\theta}{A}$$

$$R = \frac{l\,\theta}{a}$$

$$R \quad .0006015 \frac{L\theta}{D^2}$$

$$R = 1.273 \frac{l\,\theta}{d^2}$$

$$L = 1662 \frac{R\,D^2}{\theta}$$

$$L = 2117 \frac{R\,A}{\theta}$$

$$l = .7854 \frac{Rd^2}{\theta}$$

$$l = \frac{R\,a}{\theta}$$

$$D = .02453 \sqrt{\frac{L\,\theta}{R}}$$

$$d = 1.128 \sqrt{\frac{l\,\theta}{R}}$$

$$A = .0004724 \frac{L\,\theta}{R}$$

$$a = \frac{l\,\theta}{R}$$

The temperature correction may be introduced into the equation, but it complicates it considerably. The most convenient way to correct for temperature, is to calculate the resistance at zero first and then correct by means of the formula,

$$R_t = R_0 + R_0\,t\ 0.0037$$

in which t is in centigrade degrees. For reducing from a high temperature to zero, the following may be used:

$$R_0 = R_t - R_t\,t\ 0.0037$$

Neither of these are absolutely correct but are near enough for all practical purposes.

Assuming as a mean value of θ for ordinary good commercial copper, 0.0162 and assuming a mean temperature of 20° C, equal to about, 68° F. the above formulæ may be still further reduced, to the following:

$$R = .0822 \frac{L}{10{,}000\,A}$$

$$R = .0174 \frac{l}{A}$$

$$R = .105 \frac{L}{10{,}000\,D^2}$$

$$R = .0222 \frac{l}{d^2}$$

$$L = 95500.\ R\,D^2$$

$$L = 122000.\ R\,A$$

$$l = 45.1\ R\,d^2 = \text{approx.}\ \frac{90\,R\,d^2}{2}$$

$$l = 57.5\ R\,a$$

$$D = .00324 \sqrt{\frac{L}{R}}$$

$$d = .149 \sqrt{\frac{l}{R}}$$

$$A = .0822 \frac{L}{10{,}000\,R}$$

$$a = .0174 \frac{l}{R}$$

By taking the specific resistance at 0.0157 which, from the table, is seen to be still above many values given for pure, soft, copper, and therefore will not fall much below that of good commercial copper, the third one of the above formulæ reduces to the very simple and convenient form,

$$R = \frac{L}{100{,}000\,D^2}$$

if the temperature is taken at about 60° F.

Furthermore, if the diameter is taken in mils, the formula reduces to the following form, which could hardly be simpler, namely:

$$R = 10 \frac{L}{D^2}$$

in which R = resistance at 60° F. in legal ohms.
L = length in feet.
D = diameter in mils.

The resistances obtained from this formula will be slightly lower than those given in the tables of Prescott and Paine, because the temperature is taken lower, in order to reduce the constant to 10. If they are reduced to the same temperature they will be very little higher than those of Prescott and somewhat lower than those of Paine.

UNDERGROUND CABLES IN GERMANY.[1]

THE question of underground wires, which is now being agitated in American cities, has so far been answered abroad, in the affirmative, that in several countries, and notably in Germany, the underground system has even been

1. *Scientific American* Supplement.

Digitized by Google

adopted for communication between distant cities. It was in 1875 that Dr. Stephan, the director-general of German posts and telegraphs, conceived the idea of that great underground network of telegraphic cables which now connects the principal cities of the empire. The favorable results which had been obtained from the cables of galvanized iron wire, insulated with gutta-percha, which were manufactured by the well-known engineering firm of Felten and Guillaume, of Cologne, induced the government to experiment with this cable, and finally, in the following year, to adopt it in the construction of the underground line between Berlin and Halle. This was recognized as simply experimental. The distance between the two cities is 120 miles, though the connecting cable had a length of 175 miles. There were seven conductors in this cable, and consequently a total mileage of 1,225 miles. The work of construction began in March, and was completed during the following July. This line was eminently successful, and demonstrated to the satisfaction of the administration that the rapidity of transmission was adequate, and that the inductive action of the parallel currents would cause no embarrassment. In consequence, the system was extended over the entire empire, and as finished in 1880 had a total length of cable of 4,000 miles, and of conductors of not less than 28,000 miles. A portion of this network was constructed of cables composed of seven copper wires, 0.6 of a millimetre in diameter, and insulated with gutta-percha and Chatterton compound. The size and number of the conductors varied in the different cables, but were usually greater in those of later construction. The joints in the cables occurred, as a rule, once in every kilometre, and were protected by means of cast iron boxes. After the laying of each section, electrical tests were made upon the whole of the cable in place, in order to prove the joints. Ditches to receive the cable were made about one metre deep, except in those places where masonry or rock interfered, and then a depth of three-quarters of a metre was deemed sufficient. In transporting the cables, they were wound on large wooden bobbins, and were protected by a covering of straw and sheet iron. Since the establishment of the system, electrical tests have been made once every month, and show that in some cases the insulation has improved, while the oldest cable, laid about nine years ago, is as good to-day as when first laid. The cables of the entire system have been manufactured by the same firm, and have cost, in position, about $7,800,000. The example of Germany has since been followed by France, where underground cables are largely in use. They give, as a rule, the same rapidity of transmission as the aerial lines, and, from their protection from the atmosphere, are much more durable. Since the introduction of the telephone and electric light, Messrs. Felten and Guillaume have made enormous quantities of cables for these purposes. Those surrounded with lead, and insulated with impregnated hemp, are well known in the electrical world. The wire cables used on the San Francisco cable roads are also of their manufacture, and show that this well-known firm have been able to attain excellence in several directions.

In some tests made with small squares of various woods buried one inch in the ground the following results were noted: birch and aspen decayed in three years; willow and horse chestnut in four years; maple and red beech in five years; elm, ash, hornbeam, and lombardy poplar in seven years; oak, Scotch fir, Weymouth pine, and silver fir decayed to a depth of half an inch in seven years; larch, juniper, and arbor vitæ were uninjured at the expiration of the seven years.

AN IMPROVMENT ON CREMATION.

A PROCESS of preserving bodies by electroplating has been invented in France by M. Kergovaty. Successful tests have been made upon 11 human bodies, which leads to the hope that in the future we may have statues of our public men, which will be perfect, and possibly proof against the aspersions of the newspaper critic.

EXPERIMENTS ON TRANSMISSION OF POWER BY ELECTRICITY BETWEEN PARIS AND CREIL.[2]

BY M. MARCEL DEPREZ.

I AM happy to announce to the Academy that the first experiments on the transmission of power by electricity have taken place, and that the results have been very satisfactory.

The length of the telegraphic line connecting the two stations is 56 kilometres, but as the return of the current does not take place by the earth it is really obliged to traverse a line of 112 kilometres of copper cable, equivalent in section to a single wire of 5 millimetres in diameter.

The total electric resistance of this cable at the temperature of 15° C. is 100 ohms.

The generating machine is at Creil. It has two rings revolving in two distinct magnetic fields, each composed of eight electro-magnets. Each ring has a resistance of 16.5 ohms and an external diameter of 0.78 metre.

The current produced by this machine was utilized at La Chapelle by two recipient machines, situate at some hundreds of metres from each other. Only one of these recipients is at present completed. It possesses, like the generator, two rings; they have each 0.58 metre exterior diameter and an electric resistance of 18 ohms.

The experiments, begun on October 17th, took place on a looped circuit; that is, the generating and recipient machines were placed side by side, as took place in the experiments made in March, 1883, in the works of the Railway du Nord, by a commission nominated by the Academy. The objections which certain persons have raised to this manner of experimenting, which is much better adapted for scientific verification than the transmission to a distance, have been declared groundless by Tresca, with the reservation that we take, be it well understood, all the necessary precautions for measuring, during the experiment itself, the real resistance of the line, which has been actually done.

Between the generator and the steam engine which sets it in motion there is introduced a very exact dynamometer, analogous to White's dynamometer, which inscribes at each instant upon a band of paper the mechanical work absorbed by the generator. This dynamometer has been devised by M. Contamin, the engineer of the Northern of France Railway Company.

The recipient is fitted with a Prony brake, in which the heating of the friction pulley is rendered impossible by means of a circulation of water. This brake remains in perfect equilibrium for entire hours. Buss tachymeters show at each instant the speed of the generator and of the recipient. These speeds, however, remain constant during the entire duration of an experiment.

We have, therefore, all the elements necessary for determining the mechanical work absorbed by the generator as well as that reproduced by the recipient.

As for the electrical measurements, they have been taken by means of three galvanometers, perfectly graduated, and which show the difference of potential at the brushes of the generator, the difference of potential at the brushes of the recipient, and the intensity of the current traversing the two machines and the line. Two other instruments, lastly, serve for measuring the intensity of the currents produced by small exciting-machines, used for producing the magnetic fields of the generator and the recipient. The indications of all these instruments are of a great exactitude.

I will give in a future communication very complete tables, containing all the electrical and mechanical data of the experiments conducted either by M. Collignon, chief engineer of bridges and highways, or by myself. For the present I will content myself with giving the results of one of the experiments of the commission, and of another ex-

2. *Comptes Rendus.*

Digitized by Google

periment made two days afterwards in the presence of M. Sartiaux, sub-inspector of the Northern of France Railway, and engineer delegated by the commission of experiments.

FIRST EXPERIMENT.

	Generator.	Recipient.
Speed in rotations per minute	190	248
Electromotive force, direct or inverse.	5469 v.	4242 v.
Current	7.21 amp.	7.21 amp.
Work in magnetic field (in horse-power)	9.20	3.75
Electrical work (in horse-power)	53.59	41.44
Mechanical work measured with the dynamometer or the brake (horse-power)	62.10	35.10

YIELD.

Electrical	77	per cent.
Industrial mechanical	47.7	"

SECOND EXPERIMENT.

	Generator.	Recipient.
Speed per minute	170	277
Electromotive force	5717 volts.	4441 volts.
Current	7.20 amp.	7.20 amp.
Work in magnetic field	10.30	3.80
Electrical work	55.90	43.4
Mechanical work (measured with the dynamometer or the brake)	61.	40.

YIELD.

Electrical	78	per cent.
Industrial mechanical	53.4	"

It will be seen, and it is to this point that I desire to draw attention, that a useful work of 40 h. p. has been developed by the recipient with an industrial yield of 50 per cent., the speed of the generator being only 170 revolutions per minute, and that of the recipient 277. The electromotive force of the generator was about 5,700 volts. In other experiments it has exceeded 6,000 volts. These machines, therefore, develop considerable electromotive forces with very low angular velocities. It will be remarked, also, that the recipient, though having rings of only 0.50 metre in diameter, and being traversed by a current of only 7 ampères, developed a useful mechanical work of 648 kilogrammetres, without any appreciable heating. These are conditions which hitherto have not been realized.

I cannot conclude this note without mentioning the persons whose assistance has rendered these costly experiments possible; above all, Dr. Herz, editor of *La Lumiere Electrique*, who for two years has defended with the greatest energy, and by all the means in his power, the cause of the electric transmission of force to great distances, and thanks to whom, I have been able to undertake the experiments of Munich, of the Northern of France, and of Grenoble.

The present experiments, the first results of which I have laid before the Academy, have been made with the assistance of MM. de Rothschild.

The London *Electrical Review*, from which we copy the above translation, accompanies it with the following editorial remarks:

It is scarcely to be expected that the recent experiments of M. Marcel Deprez, which was fully dealt with in our other columns, will excite the same amount of interest, we might almost say sensation, as the results of his previous experiences between Miesbach and Munich, Vizille and Grenoble, and other places, notwithstanding the fact that they are of a more grotesque and fantastic character. We are now so conversant with matters involving the transmission of power by electricity, that the results obtained through the dogged determination of the French electrician to overcome the many obstacles with which his path has been beset, will fail to arouse any degree of enthusiasm, at least on this side of the channel. What with the Portrush tramway, a similar line between Bessbrook and Newry, the telpher system at Glynde, &c., the public has long been convinced that the electrical transmission of power could be readily and successfully undertaken. We do not, of course, intend to lead our readers to think that the operations carried out in this country can compare in magnitude or distance traversed with those of M. Deprez, but we do mean that had any of our electrical engineers received such support and assistance as has been accorded to him the same thing could as readily have been accomplished in England in much less time, and, we think, in a manner less open to criticism. We notice that M. Deprez still adopts the plan of putting his apparatus in a looped circuit, and this in itself is enough to make one doubt the accuracy of his tests, unless the line were perfectly insulated, which we need not say could not have been the case. To have obtained the results with which the French engineer credits himself, his generator must have been capable of reproducing nearly 80 per cent. in the external circuit of the mechanical power exerted in driving it, and the recipient must have converted nearly 80 per cent. of the electrical energy received into available power. We have not had M. Deprez's figures before us sufficiently long to enter deeply into the matter here, but in a future issue we shall take occasion to go more fully into an impartial examination of his tabulated results. The idea, however, of separately exciting the field-magnets of the motor is an absurdity upon which we need not enlarge, for in practice the motor must decidedly be self-acting in this respect.

We may in conclusion state that, so far as we can judge at the present moment, M. Deprez's figures will not bear a careful analysis.

BUFFALO ELECTRICAL SOCIETY.

At the regular meeting of the Buffalo Electrical Society held at their rooms Friday, November 6th, Prof. A. L. Arey delivered the ninth of his course of lectures, the subject for the evening being "The Divided Circuit."

The lecturer began by deducing the well-known formula for the resistance of a divided circuit,

$$R \frac{r\,r^1}{r+r} \qquad (1)$$

in which $R =$ the joint resistance of the two arms, r the resistance of one arm and r^1 the resistance of the other arm, and continued, remarking that in the majority of divided circuits the several arms or branches are of equal resistance, as in the case of incandescent lamp circuits or of batteries connected in multiple arc. We have in such cases $r = r^1$ and the formula (1) becomes

$$R = \frac{r^2}{2r} = \frac{r}{2}$$

but 2 is the number of branches, and if we let $n =$ the number of branches we may write

$$R = \frac{r}{n} \qquad (2)$$

by means of which we may determine the resistance of any divided circuit.

To illustrate the application of this formula the following problem was solved:

What will be the resistance of 900 incandescent lights, each having a hot resistance of 130 ohms connected in simple multiple arc?

Substituting in the formula

$$R = \frac{130}{900} = 0.144 \text{ ohms.}$$

After applying this principle in connection with Ohm's law to several more complicated problems, Mr. Arey stated that the consideration of a large class of problems seemed to have been overlooked by the various writers on electricity, and gave the following deduction of formula for the determination of the number of cells of a given

Digitized by Google

battery which will produce a given current through a given external resistance, and the manner in which they must be connected.

In problems of this kind we have given

C = the current desired.
R = the external resistance.
e = the E. M. F. of the cell.
r = the internal resistance of the cell.

Let

x = No. of cells in series.
y = No. of rows of cells.
P = internal resistance of battery.
E = the E. M. F. of the battery.

By Ohm's law we have

$$C = \frac{E}{P+r} \qquad (3)$$

but the E. M. F. of the battery is equal to the E. M. F. of one cell multiplied by the number of cells in series; hence

$$E = ex$$

substituting in (3)

$$C = \frac{e\,x}{P+R} \qquad (4)$$

and since the maximum current is obtained from a given battery when its internal resistance is equal to the external, we may determine the smallest number of cells which will produce the given current by making $P=R$ in equation (4); hence

$$C = \frac{e\,x}{2\,R} \qquad (5)$$

clearing of fractions

$$e\,x = 2\;C\,R$$

$$x = \frac{2\;C\,R}{e} \qquad (6)$$

The resistance of the given battery will be

$$P = \frac{r\,x}{y} \qquad (7)$$

but since $P=R$ we may write

$$R = \frac{r\,x}{y} \qquad (8)$$

clearing of fractions

$$R\,y = r\,x$$

$$y = \frac{r}{R}\,x \qquad (9)$$

substituting the value of x found in (6) in equation (9) we have

$$y = \frac{r}{R} \times \frac{2\;C\,R}{e}$$

whence

$$y = \frac{2\,C\,r}{e} \qquad (10)$$

and we may obtain the number of cells which must be connected in series by the equation (6)

$$x = \frac{2\,C\,R}{e}$$

and the number of such series by equation (10)

$$y = \frac{2\;C\,r}{e}$$

Of course the number of cells used will be equal to x multiplied by y.

It is evident from an inspection of the formula that the number of cells in series depends upon the external resistance while the number of such series depends upon the internal resistance of each cell.

In conclusion the following problem was solved to illustrate the application of the formulæ:

How many gravity cells will be required to send a current of 10 ampères through a resistance of 5 ohms, and how must they be connected, assuming the E. M. F. of each cell = 1 volt and its internal resistance 1.5 ohms?

Substituting in (6) and (10)

$$x = \frac{20}{1} \times 5 = 100$$

$$y = \frac{20}{1} \times 1.5 = 30$$

therefore the number of cells required will be 3,000, connected in 30 rows of 100 each.

THE TELPHER LINE AT GLYNDE.[1]

On Saturday Oct. 17, was witnessed a practical demonstration of one of the most interesting outcomes of modern electrical engineering which has yet been brought publicly forward. We refer to the opening of the first telpher line erected in this country, on the estate of Viscount Hampden, at Glynde, a small village within three or four miles of Lewes, in Sussex. The directors of the Telpherage Company had invited a considerable number of guests, amongst them being many representative men of science and of the press, together with a sprinkling of ladies and gentlemen from the surrounding neighborhood.

The London contingent went down to Glynde by a special train from Victoria, and on its arrival, at 1.20 P. M., the guests were conducted to the engine house, whence they could obtain a good view of the starting gear and the telpher train. Shortly before 2 o'clock the line was formally opened by Viscountess Hampden, who, on lifting a bracelet with which she had been presented from the table at which she stood, made connection from the dynamo to the line, when the electric locomotive immediately started upon its journey with its attendant train.

As the system of telpherage invented by the late Prof. Fleeming Jenkin, in conjunction with Professors Ayrton and Perry, has been very fully described and illustrated in various numbers of the *Electrical Review*, notably in the issues of Dec. 8th, 1883, and May 31st, 1884, we need now only remind our readers that it has for its object the automatic electrical transport, along an overhead steel rope or rod, of goods, such as minerals, ores, slate, grain, roots, manure, or in general any goods easily divisible into parcels of from 2 to 5 cwt., at a cost greatly less than that of cartage. As a matter of fact the line at Glynde has been constructed for carrying clay at 7½d. per ton to a siding at the railway where it is tipped into trucks waiting to receive it, and conveyed to the works of the Sussex Cement Company, in Newhaven.

The Telpherage company, which possesses the patent rights of Professors Jenkin, Ayrton, and Perry in telpherage, has, as our readers are aware, experimented on a large scale at Weston, on the estate of the chairman, M. R. Pryor, Esq. Prof. Jenkin died in June this year, leaving his plans of the Glynde telpher line to be carried out by Prof. Perry, his successor as engineer to the company. These plans have necessarily been modified somewhat during the erection of the line, but to as small a degree as was possible. The line is a double one, nearly one mile long, composed of a double set of steel rods, each 66 feet long and three-quarters of an inch in diameter, which are supported on wooden posts at an average height of 18 feet above the ground.

The distance apart of the up and down lines is 8 feet. The two ends of the line are of bulb-angle steel, with supports 13 feet apart. Hanging from the rod a train of ten skeps or buckets, drawn by a locomotive, passes on to the charging end, where it is stopped at any desired place. The skeps are then loaded. Each of the ten skeps weigh 101 lbs., and contains 250 to 300 lbs. of clay in dry weather. At the will of a laborer, who touches a key, the train starts, and travels to the railway station at the rate of four to five miles per hour. On the opening day each of the skeps was upset as it came over a railway wagon by a laborer, at

1. *Electrical Review* (London).

Digitized by Google

whose will the train can be stopped or reversed; but this upsetting will afterwards be performed automatically. One train will deliver the minimum amount of clay (150 tons per week) required by the Cement company. If necessary, 20 trains can run on the line without its being possible for one train to collide against another, there being an absolute automatic block provided. The trains need no attention when running, as they are governed to run at the same speed up hill and down hill, and there is also the above mentioned automatic block.

The initial source of power is the Ruston and Proctor engine, formerly used in the Weston experiments, and controlled by a Willans's electric governor; this drives a Crompton's 6 "unit" shunt wound dynamo.

The maximum difference of potential is 190 volts; the current for one train is 8 ampères, two trains need 16 ampères, and so on.

The Reckenzaun motors run in parallel arc. The resistance of the rods used to support the train and convey the current is moderate compared with the resistance in each motor, and the motors have an electromotive force which is large relatively to that produced by the dynamo; consequently, there is little difference in the electromotive force available to drive the several motors, whether these are near the dynamo or far from it; extreme constancy is, however, quite unnecessary under the actual conditions of working, which in this respect are unlike those of electric lighting. The speed and power are controlled by a centrifugal governor of novel construction on the locomotive. The weights and springs are so combined as to be in unstable equilibrium at the critical speeds. Thus, at say 2,100 revolutions per minute, the weights will fly out, breaking contact sharply and widely; they will not return till the speed has fallen to say 1,900. By this plan a permanent arc to the contact is avoided. Injury to the contact pieces is prevented by providing a carbon rod as a secondary contact. This rod is very slowly consumed. The plan described not only regulates the speed, but distributes the power in the ratio required by the several motors. While ascending a steep gradient the current will be on for almost the whole time; while descending a steep gradient it will be off altogether; on level lines it may be on for say a quarter of the whole time of running; this plan avoids all waste in shunts or interposed resistances, and has been tested with good results. The current cut off by each governor is too small to injure the dynamo.

It is claimed that the telpher line will find its application in all cases where the traffic is sufficient to pay interest on a small outlay, and is insufficient to pay for the construction of even the cheapest form of railway. The road and trucks closely resemble the road and trucks already employed for over-head wire rope tramways; but instead of dragging the trains along by means of a wire rope, they are driven by very simple electrical arrangements. By employing electricity the following advantages are gained:—The road is simpler and cheaper, as there are no pulleys or working parts, and no second rope is required; the maintenance is cheaper; there is nothing to oil, and no working parts to wear out; the direction of the electrical road can be changed as often as is desirable, so as to follow a winding direction, an object difficult of attainment even to a moderate extent with rope haulage; the gradients in the electrical road may be as heavy as one in eight, and these gradients may vary as frequently as is desired, which is not possible, except with complicated arrangements, in rope haulage; finally, the power required will be less, except in the simplest cases of rope haulage. In addition, the electric power can easily be tapped *anywhere* along the line and used for working agricultural or other machinery simultaneously with the propulsion of the telpher trains. This facility was shown in practice on Saturday last by a small Ayrton and Perry motor, weighing 33 lbs., attached temporarily to one of the posts of the line, working a turnip-cutter.

As compared with light steam railways, the telpher lines have the following advantages:—They are cheaper, requiring less metal than the lightest rails. No earthworks, bridges, culverts, drains, or fences are required. No land need be purchased. Much sharper curves can be employed. No attendant is required to accompany the trains. Telpher lines crossing a farm will not materially interfere with the cultivation of the land.

The same advantages are claimed over electric railways with this further advantage, that the required insulation is easily obtained when the lines are suspended like telegraph wires. The electrical current required for a moderate traffic would be harmless, and in any case the suspended line is well out of the way of mischievous or accidental interference. The power required to work these lines may be obtained from any steam engine or water-wheel. A single train conveying from 10 cwt. to 20 cwt., according to the gradients, will in general require about three horse-power at the source of power.

In some cases, and notably at the stations and long curves, it is desirable to run the trains on stiff rails. Trains driven by electricity along a *single* wheel-path were absolutely novel at the date of the first telpher patent, in which both the flexible and rigid road are described. Full details of both have been worked out and tested in practice, and a trial train at Weston, Hertfordshire, has run some hundreds of miles, and has been seen by numerous visitors.

A line like that at Glynde could now be erected at short notice for a total cost of £1,200, including engine, dynamo, permanent way, stiff ends, and five trains with locomotives, to carry over 100 tons daily. The working cost, including coals and wages of stoker and electrician, and 12½ per cent. on cost for interest and depreciation, would be less than threepence per ton of material carried, the skeps being empty on their return journey.

A double line like that at Glynde, but ten miles long, if heavily worked, will carry material at twopence per ton per mile, the skeps being empty on the return journey. One very important feature in respect of the cost of telpher lines is the fact that the larger part of the cost is due to plant, such as locomotives, trains, and dynamos, which can be increased in proportion to the work required; thus there is a very moderate increase of cost in the rate per ton per mile for a small traffic as compared with a larger one. And on the other hand a line laid down for a small traffic will accommodate a much larger traffic with no fresh outlay on the line itself.

A single engine and plant of dynamos and trains might work many circuits radiating from one centre, and under these circumstances it would pay to erect lines intended only to be worked to their full capacity for a couple of hours each day or for one day in a week. In fact the function of the telpher line is not to compete with railways, but to do cheaply the work of horses and carts.

The day finally appointed for the opening ceremony was not a favorable one. It had been raining heavily early in the morning, and at intervals during the trials an unpleasant drizzle was noticeable, yet the running of the train passed off quite satisfactorily.

STORAGE BATTERY PLATES.

A correspondent of the *English Mechanic* gives the following as the best form for a storage battery :

Lead plates 4x6 inches are bored with very small holes about ⅛-inch in diameter all over, and a flap of lead is left projecting at one end for connections. The holes are filled with a paste of red lead mixed with water, and they are dipped in dilute sulphuric acid (1 to 10) two or three times, and allowed to dry. When dry they are placed in jars containing dilute sulphuric mixed as before. They are then "formed" by passing a current from a dynamo through them, discharging through some resistance, and then charged the reverse way. This is done for several days—sometimes a week. After formation they are always charged the same way.

LITERATURE.

REVIEWS.

American Electric Manufacturing Company and its American System of Arc Lighting; pamphlet, 42 pages, illustrated. New York: Twenty-third street and Fifth avenue.

This publication, although intended for gratuitous circulation, will be found of much interest to all who are identified with electric lighting, either as producers or consumers. It treats principally of the apparatus furnished by the American company, but the general arguments in favor of electric lighting are clearly and forcibly put.

In his advice to representatives and agents the president states very strongly and properly that the business of electric lighting demands the full time and energies of the individual. It should not be a side issue.

The company undertakes to furnish everything required for the complete equipment of a central station. The number of arc lamps of all kinds used in this country is placed at over one hundred thousand, which, however, is considered but a beginning. The dynamos and lamps now being introduced are of the Fuller-Wood type, and are made at the company's factory, 163 and 165 West Eighteenth street, in this city. The regulations for installations established by the New York Board of Fire Underwriters are given in full, also those of the New England Insurance Exchange. Those desiring to learn the merits of the American system, or general information on the subject of electric lighting, will be supplied with a copy upon addressing as above.

In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

WIRE DISTRIBUTION IN CITIES.

[42.]—I have read with much interest the plan proposed by Mr. Ries in your last number, for carrying and distributing electric conductors, etc., in cities, and have been much impressed with the original and thorough manner in which the subject has been handled by him. While not desirous of criticising the arguments made and conclusions arrived at by Mr. Ries, yet there are one or two points upon which some objection may be made. While the system of overhead main and branch ways proposed may do very well for cities not already provided with elevated railways, it is not clear that this system could be carried out in New York and Brooklyn, which are the cities principally affected by the underground legislation, and in which the overhead obstructions in the form of elevated railways, will be more difficult to overcome than the gas and water pipes. I would suggest that if the main and branch conduits were buried *below* the level of the water pipes and sewers, that Mr. Ries's plan of distribution, which in other respects appears to be admirably adapted to the needs of the different classes of conductors for which it is intended, would be open to less objection and be of a more permanent character than if erected above the street surface.

QUESTIONS AND ANSWERS.

[71.] **Treatment of Leclanche Disque Cells.**—H. E. P. writes that he has eight of these cells, which have never worked more than 15 minutes at a time. He has taken the filling out of three porous cups expecting to find them coated, but they were not. He now wishes to refill them properly. Ans.—Place the carbon plate in the centre of the jar; crush a sufficient amount of carbon into various sizes—from the size of a pea down—and pack the larger pieces in layers in the jar round the carbon plate, so that the particles are in firm contact among themselves, and with the central plate. The finer grains should be mixed with three times their bulk of manganese also in fine grains, and as each layer is packed, the mixture should be sifted in to fill the interstices. The fine powder of both ingredients has to be sifted out because it resists the penetration of the liquid. Before filling, the porous cups should be well soaked in hot water acidulated with sulphuric acid to remove any crystallization which may exist in them. Hard or partially glazed porous cups should not be used. The exciting solution should be composed of from 4 to 5 oz. sal-ammoniac and sufficient water to reach to about an inch below the shoulder of the glass jar. The solution is frequently allowed to become too *weak*. If crystals accumulate on the zinc—it is a sign that *more* sal-ammoniac is needed—these crystals are usually an oxychloride of zinc and will not deposit if the liquid is kept at proper strength. A few drops of sulphuric acid occasionally put into the compound in the porous cup will prove advantageous as it neutralizes the alkali accumulating therein. All "open circuit" batteries suffer from overwork. They are not intended for "closed circuits."

NEW YORK AND VICINITY.

Activity of the Competing Quotation Companies.—Another Trial of the Daft Motor on Ninth Avenue.—Electric Light Operations in New Jersey.—Operator Pratt Secures Bail.—What the Brooklyn Subway Commission is Doing.—Progress of the Long-distance Telephone Line.—Gas in a Western Union Man-Hole.

THE competition between the rival "ticker" companies which at one time might have been based upon the difference in the prices of the service, has now become a struggle for the survival of the fittest. As soon as arrangements were completed by the Stock Exchange to furnish quotations simultaneously to the Gold and Stock and Commercial Telegram companies, it was evident that success could be obtained only by the most prompt and accurate transmission. To meet the emergency, the Gold and Stock Telegraph Co. was fortunately well prepared, and on the 3d of November the introduction of the Scott printers was actually begun.

Digitized by Google

The number of instruments placed upon a circuit averages 28, or about double the old style. The new circuits are also metallic instead of grounded, a tardy recognition of the merits of this plan, which was adopted in the same field by the Laws reporting telegraph 17 years ago. The first circuits changed were those in the vicinity of the Stock Exchange, and the work is proceeding as rapidly as possible, with the prospect of being thoroughly completed by the 1st of January. The machines are driven by a dynamo current, their speed being fixed at the medium capacity of 174 revolutions per minute, with a possibility of increasing to 250 as the operator acquires familiarity with the key-board.

Meanwhile the Commercial Telegram company has also put its best foot forward, and has made the most of its opportunity. The superior speed of its new tickers over those heretofore in general use by its rival, afforded an opportunity to gain patronage which was promptly availed of. Whatever may be the financial result of this contest it will certainly leave behind it a vastly improved service, which is a far more substantial gain than can be shown by competition in any other branch of the telegraph service.

Another invitation exhibition of the Daft motor was given on November 18, at which two car loads of people were present. With the usual misfortune that proverbially attends trials of this character, a brush burnt out, causing a delay of eight minutes on the trip from 14th to 50th street on the Ninth avenue elevated railway. The return trip was made in seven minutes, the quickest time yet made in a public test. Among those present were Sidney Dillon, Edward H. Johnson, Cyrus W. Field, A. S. Brown, Whitelaw Reid, and about 20 members of the American Society of Civil Engineers It had been announced that this was the final trial previous to placing the motor in regular service on the road, but none of the gentlemen present, were prepared to state officially when it would be put in operation as part of the motive power of the Ninth avenue line.

The Brush Electric Light Co. in Paterson has been comparatively prosperous in its undisturbed occupation of the field, but the people as usual consider themselves heavily taxed, and it is reported that a new company is about to be organized which will supply lights at half the price. This is not carrying out the principles which were so heartily supported at the recent meeting of the National Electric Light Association, where it was the general feeling that fresh fields should be sought rather than cut-throat competition where plants were already established.

The Elizabeth Schuyler Electric Light Co., although not yet in actual operation is progressing with its work, and has put in its bid for the public lighting of the streets of Elizabeth. It offers to supply arc lamps in groups of four, equivalent to 32 gas lights for $125 per year for each lamp, to burn from dark until one o'clock. Poles are now being erected for the installation of private lamps, and it is quite probable that electric lighting will be adopted for the streets if the additional expense is not too great.

Thomas B. Pratt the telegraph operator on the Meadows, through whose mistake the collision of Oct. 8 occurred on the Pennsylvania railway, has secured $5,000 bail for his appearance at trial. Although liable to ten years imprisonment, it is doubtful whether the fear of punishment of this nature will have a tendency to diminish accidents in future. No legislation can secure immunity from human errors.

The Brooklyn Subway Commission has consented to the issue of a joint permit to the fire department and the New York and New Jersey Telephone company, to erect about 300 poles for telegraph and telephone wires in various parts of the city. The telephone company puts up the poles, giving the city a joint interest in them and the right to string its wires upon them. Commissioner Fleeman has granted a permit for the erection of the poles. The telephone company has also begun operations on Fulton street, Brooklyn, for a new conduit, which when complete will run up Main street to Fulton and thence to Flatbush avenue, to Third avenue, to Atlantic street. The new system will not be in operation before January. There are about 9,000 feet of the conduit to lay.

The poles have been distributed through Bayonne city, New Jersey, for the line of the American Telephone and Telegraph Co., but an injunction has been served in the interest of Rufus Storey, a large property holder, which will hinder operations until some kind of a settlement is reached. This line is intended for the introduction of long-distance telephony between the cities of New York and Philadelphia, and its progress will be watched with interest, as the business between these two points is of a character to make the enterprise a success if it can be attained anywhere in the country.

When the underground cables were laid for the fire department last month, connection was made with one of the Western Union man-holes on Broadway. As soon as an opening was made in its side a stream of gas poured out which caught fire from a lantern and severely burned one hand of Mr. Pearce, firm of Pearce & Jones. By rapidly filling in with dirt the flame was soon extinguished. Fortunately no explosion occurred.

NEW YORK, November 20th, 1885.

CHICAGO.

Agitation Regarding the Use of Areaways for Wire Distribution.—Proposed Construction of Lateral Conduits Round the Blocks.—The Milwaukee Authorities Visit Chicago for Information.—An Underground Company in St. Louis with $600,000 Cash.—The Chicago Conduit Company Refunds $10,000 to the City.—Lighting of the City Hall.—Extensive Central Plants now in Operation.—Time Distribution by the Telephone Company.—Mr. Badger's Contract with the American Electric Mfg. Co.—Proposed Illumination of the River.

ELECTRIC light companies and western city councils are still having plenty of amusement in trying to come to some finality in the matter of getting to individual customers. The underground system here was thought to cover it all, and now companies are troubled to get from the main conduits into the buildings. Everything seemed to be running all right, until the idea struck somebody that a little something in the form of a "come-and-see-me" would be appropriate, inasmuch as the electric light people were making such mints of money out of their enterprises! So, to find a good excuse for the enforcement of voluntary contributions, the dear people have set up the hue and cry that the insurance risk would be largely increased by allowing light wires to cross private premises. The scare, or the hint, or both, became general, and it is perfectly astonishing how many of our good citizens have discovered within the past few days that they are liable to be burned in their beds, "now, and immediately," if these incendiary electricians and underground people are allowed to run their cables—even where these are inclosed in iron or other pipes—under the sidewalks and in areas.

Prof. Gray, who, as an eminent electrician and the head of the Underground Conduit company, has given the subject much attention, is perhaps as well posted as any one. In an interview with the representative of one of our daily papers, Professor Gray said :

"The misapprehension on the part of the real estate men and property owners in Chicago regarding the use of areaways in connection with supplying their buildings with telephonic and other electrical conveniences, seems to arise from statements made by unauthorized parties that this company is going to construct its system of conduits under the sidewalks, and in so doing will take possession of and occupy a large portion of the areaway now controlled by the property holders ; and by so doing interfere with the boilers, etc., constructed under areaways for heating and furnishing power for elevators and other purposes. It is also stated that a private corporation is to usurp these rights in spite of the protests of private individuals."

The city's legal authorities sometime since rendered an opinion on the subject of street boundaries which gave the building line, or inner line of the sidewalk as the boundary line of the street—in other words that the walks as well as the streets are included in the franchise of the Underground Conduit Co.

This discovery, and a proposed amendment to the underground concession ordinance was what brought about the present muddle, which a few days will undoubtedly solve, and then the last obstacle to rapid advancement in electric lighting in Chicago will have been removed.

When it is considered that only a very small portion of any areaway or coal cellar will be needed—barely room for a small iron tube or two, to contain all the wires necessary for the electrical supply of every nature—when this will be run as a rule in a right angled corner, the same as a service gas pipe, it does seem that there is much cry and very little wool in this whole agitation.

The proposition has been made and will perhaps be carried through, to arrange for lateral service pipes placed at the upper inside angle of the curb wall and sidewalk flagging, with proper conveniences for tapping these to supply the buildings. These lateral pipes will run thus entirely aroumd the block, so that there will be no necessity for touching them, once they are in, except to connect or disconnect a customer's individual wires.

There will be no running over the roofs when this is finished, and it will do away with the wires running up and down and across buildings; and furthermore, the wires will be out of the weather as well as out of sight—only the dampness will remain to be feared, and that properly cared for is entirely innocuous.

Eighty-five miles north of us is another corporation which is having a great "to do" about electric lights and underground wires. The fact that two electric light companies from here had applied for franchises in Milwaukee has been chronicled in these columns, and the veto of the Badger ordinance was also recorded. Immediately on the failure to carry the question over the veto a second Badger ordinance was drafted for presentation, and also a Sperry ordinance.

Then the committee and several other members of the council, headed by the president, several city officials and a news-gatherer, of course, came to Chicago to look around and see for themselvs. The party were met on the evening of the 2d instant by Mr. Dorsett, and piloted to the Tremont House for supper, which, though

elaborate, was despatched in a strictly business, though cheerful manner—the haste on the occasion arising from the necessity of getting into the street before the electric lights were extinguished. The party left the hotel under the guidance of our city electric light inspector, who was enabled to show them such an exhibition of lights as they had never seen or anticipated, where these are in regular nightly service. The following day Mr. Dorsett went through the entire conduit business, including the manufacture and handling of the Dorsett conduits and a careful examination of the pipes in the streets.

Chief Fire Marshal Swenie also took a hand in chaperoning them through the fire alarm and police systems, so that when they were back on the train and had time to draw a long breath they had something besides politics to occupy their minds and to talk of on their way home.

On the Friday following an ordinance was prepared by the judiciary committee for submission at the next meeting of the council, which grants a franchise to the Dorsett underground company for the city of Milwaukee. This ordinance is thoroughly satisfactory to all who have heretofore been inimical to underground ordinances and systems of all kinds, and will without doubt be passed and signed without delay. By its provisions work is to be commenced at once, and its early completion is assured.

So, too, in St. Louis the organization of a Dorsett underground company has been completed, and the sum of $600,000 to cover the capital stock, has been placed in the Commercial National Bank to the credit of the organization.

In the matter of investigation by our city council into the ways of the Chicago Sectional Underground Company, the matter has so far progressed that the company has seen the error of its ways, and has refunded the $10,000 which the city had paid for conduit privileges for the city wires. The franchise will be amended in due time.

Our city hall was lighted up for the first time on the 9th inst., on the occasion of the regular meeting of the council. The plant is an eminent success in every respect.

At that meeting a communication from property holders was read and referred, asking that the council delay temporarily any action on the sidewalk area question, and await further information from the communicants. It is understood that a huge petition or remonstrance, or something on the subject will be forthcoming shortly which will once more stir the matter from its uttermost depths.

The telephone investigation is a town topic, and, taken in connection with other electrical topics and arguments, makes it quite apparent that we are fast becoming a community of electricians. The next edition of the electrical directory will not be permitted to stop at dynamo runners and repair men, but will have to include *all* the "butchers and bakers and candlestick makers" in the business as electricians.

The Schuyler central plant on State street is in effectual operation and the lights are doing good service.

Chicago can boast of several quite extensive central plants for electric lights. One of these starting from Monroe street runs to Lake, with lights on Clark, Dearborn and Randolph; another commencing between Monroe and Madison runs north and south between Monroe and Washington with lights on Clark, as well as the streets above mentioned; one on State near Washington works its way north past Randolph nearly to Lake, south to Madison and Clark, with lights on all these thoroughfares, and a second plant on State street further south takes in several blocks both sides of the street; while one on the west side near Halsted, runs lights east, west, north and south of the dynamo. In prospective there are several other extensive central plants awaiting only the council's action relative to the sidewalk question.

The Central Union Company has placed in a little box inside the regulator clock at Giles Brothers' establishment one of Oram's time distributors, which gives time on all telephones in their district, five; and in any one of the other districts it can often be caught by secondary induction. Where this can not be done, it is only necessary to ask a connection with some one in district five, and exact time can be obtained at any minute.

The noise of the induction buzzer is not sufficiently loud to interfere with conversation, but is distinct and unmistakeable. The method of designating the ciphers in ten, twenty, thirty, etc., is ingenious. The time being 2.30 for instance, at the instant the second hand completes the minute a sharp, short buzz is heard, then two strokes, and quite soon afterward three strokes of the buzzer. In the case of 2.03 the strokes are the same, but a longer space between the 2 and 3 is the distinguishing feature.

Mr. S. S. Badger, who is the head of the Badger company here, running one of the central plants above mentioned, has heretofore used the Thomson-Houston system for all his circuits. Mr. B. has recently closed a contract with the American Electric Manufacturing Company, which makes him their western agent, with a branch office in Chicago. This arrangement turns over to that company Mr. B.'s plants, not only in Chicago but in several other Western cities, where, according to the *Scientific American*, there are so many people suffering from "adamantine credulity," poor things!

That great drawback and time-wasting institution, river crossings, while a necessity at present, is becoming daily more serious. While it must be granted that the shipping interests are vital to our prosperity, there are thousands of hours lost daily to our citizens, either in starting too soon or arriving too late, in evading or suffering from bridge delays. Heretofore it has been perilous to think of thwarting the sweet will of the shipping interests, but a late ordinance of the council prohibits the opening of bridges from 6 to 8 in the morning and 5 to 7 in the evening. This is looked upon as the entering wedge, and it is now proposed to light up the river banks by electric lights, and then urge an ordinance restricting all outgoing vessels from passing through the river during daylight. Vessels arriving will of course be permitted to make harbor.

There will be considerable commotion when the great day comes; but something must be done soon or a general uprising of the people on this question is imminent. There is too much of it, and it comes too often.

CHICAGO, Nov. 17, 1885.

PHILADELPHIA.

The Baltimore and Ohio Seeking Equal Telephone Rights.—The Electrical Railway Nearing Completion.—Applications for Rights of Way Over and Underground.—Appropriations for City Electrical Work.—Rumors of a Telegraphic War of Rates.—The Novelties Exhibition.

JUDGES Thayer, Arnold and Wilson on Saturday listened to arguments on the mandamus proceeding by the Baltimore and Ohio Telegraph Company to compel the Bell Telephone Company of Philadelphia to put a telephone in the office of the former corporation, at No. 227 Chestnut street, so that it can be used for receiving from its customers telegraphic messages to be sent over its lines. The contention of the telegraph company is that the telephone company does such service for the Western Union Telegraph company, and to deny the same facilities to it is unjust discrimination. The answer of the telephone company is that the Baltimore and Ohio company has no right to exact extra work, as claimed—work that ought to be done by messenger boys.

In addition to this, the telephone company says that it is simply the licensee of the American Bell Telephone Company, and is subject to a contract which the latter has with the Western Union Telegraph Company. By this contract the Western Union has the exclusive right to use the Bell telephone patents, and, therefore, to give the Baltimore and Ohio Telegraph Company the same facilities would be a violation of a solemn contract. To this it was answered that such a contract is in restraint of trade and is, therefore void; that the business of the Bell Telephone Company of Philadelphia, is analogous to that of common carriers, and that, as between it and persons to be served, no contract can intervene, which gives a preference to one over another. The matter was held under advisement.

The American Electric Company are fast completing the experimental line of road on Ridge avenue, between the car depot at 32d and Dauphin streets and West Laurel Hill. The work is progressing at the rate of about 350 feet a day on the south track. The conduit that is being laid is only four and one-half inches wide by nine inches deep, and is laid on concrete, covered with a layer of Portland cement. Sewer connections at intervals permit the washing out of the slot and also carry off the rain water. In the conduit on each side of the slot runs a copper conductor, one-fourth of an inch wide by one inch deep, on the bottom of which runs a grooved piece of cast iron. Running in the slot, supported by two wheels, is what is called a traveler. This is provided with two springs, which run along the cast iron on either side, receiving the electric current.

In the station an engine supplies the generator with power, which is transmitted to the motors, one of which is on each car, by the process above described. Each car is provided with four electric lamps on the inside, and an electric headlight on each end on the roof. The speed is regulated by the man in charge of the car, and it is possible to make it almost that of a locomotive.

The road that is now being laid will probably be in running order by the latter part of next week. It is entirely experimental, but the experiments will last through the winter. The American Electric Company, should the road prove the success they anticipate, will, during the winter, erect shops where they may manufacture their own machines. Those they have at present were made by the Schuyler Electric Light Company, of Hartford, Conn. The estimated cost of an electric railway 10 miles long with 50 cars is $147,000. This includes machinery in the depot and on the cars, cost of laying and cost of material; but not the cars themselves. The total cost of running is $33,494. The cost per day is $92 for the whole line, or $1.84 per car. As opposed to this is the following estimated cost of the cheapest and worst horse car line in the city, estimated as low as the conscience of the president would allow: Cost per year for ten miles of road and fifty cars, $86,775;

Digitized by Google

cost per day, $237.74 for the whole line; cost for one car by the day, $4.74. This is exclusive of any salaries. The electrician in charge of the new work is William B. Schlessinger.

The Electrical Committee of Councils met in chief Walker's private office yesterday afternoon. An ordinance authorizing the People's Telephone Company to stretch their wires along the streets of the city was considered and referred to a sub-committee for examination. Another ordinance, granting permission to the American Telegraph and Telephone Company to lay underground pneumatic tubes, conduits and cables under the streets of the city was submitted. It is the company's purpose to run a cable under the Delaware, and lay their wires underground on Walnut street to Fourth and thence to the offices of the Bell Telephone company. This, it is declared, will give subscribers direct telephone communication with New York. The ordinance was directed to be reported to councils with a favorable recommendation.

The appropriation for the department for the year 1886 was considered. The appropriation for 1885 was $84,407. The sum asked for 1886 is $149,200, an increase of $64,793. There are two main items on which the increase is asked. One is for $30,000 for additional electric lamps and the other is for $30,000 for putting the city wires underground. The electric lamps already in use cost the city $39,000 a year, or an average of $182 a lamp. These items were passed by the committee, although several members declare that they do not believe that any practical invention for the successful operation of wires underground has been discovered.

Rumors are again current that the Western Union Telegraph Company propose to inaugurate a vigorous war against the Baltimore and Ohio. The low schedule of rates adopted by the Baltimore and Ohio is to be met by a cut to a 5 and 10-cent rate by its great competition. Ten word messages, according to the statement said to be vouched for by Western Union officials, are to be sent within the territory between Boston, Philadelphia, New York, Baltimore and Washington, and including the New England states, for 5 cents, and the 10 cent rate is to extend from the Atlantic coast to Chicago, St. Louis, Cincinnati and other western cities. The officials of the Western Union in this city say that they have heard of no such scheme, and that they do not believe that such a cut is contemplated.

The regular monthly meeting of the Franklin Institute was held last evening. Professor Houston presented two photographs taken on a dark night by the light produced by flashes of lightning; in which a building and trees were distinctly shown. They were thrown on the screen by the aid of professor Holman's lantern microscope. The duration of the flash by which the plates were secured was estimated at the one three hundredth part of a second.

Mr. H. R. Heyl, of the managing board, presented the statistics of the late Novelties exhibition. The total attendance was 145,000, and the gross receipts $43,000. The expenses have not yet been fully ascertained.

Speaking of the exhibition of 1886, Mr. Heyl said: "It is quite certain that a prominent feature in the display next year will be an exhibition of gas industries. The convention of gas men was held in Cincinnati this year, and will be held in Philadelphia in 1886. At the Cincinnati convention it was considered advisable to consult the Franklin Institute board regarding the incorporation of gas exhibits in the Novelties display, and the board unanimously adopted the suggestion.

PHILADELPHIA, November 19, 1885.

BOSTON.

Public Fire Alarms in Disfavor.—A Visit from the Director of the Paris Fire Brigade.—A Burglar Caught in the Act.—The Police Authorities Investigating the Police Patrol System.—Proposed Electric Tramway between Boston and Nahant.—Public Electric Lighting in Lawrence.—Prosperity of the International Telephone Co.—The Massachusetts Telephone War.—Telephone Rentals to Different Municipalities.—Property of the Telephone Syndicate Attached.—Arraignment of Henry K. Goodwin.—Telephone Stocks.—Long-distance Telephony.

THE Boston fire commissioners are considering the advisability of discontinuing the striking of bells in the city proper in case of fire. All companies of the fire department in this section of the city are permanent companies, and the members are notified of fires by the striking of gongs in the houses of the department. The proposed change would prevent the annoyance now caused to many who live near a fire bell or have offices in the vicinity of one.

M. Paul Garcien, director of the fire brigade of Paris, who is studying the apparatus and methods in vogue in the government of fire departments in this country, was received by a committee of the city government last week and entertained at the Parker House. Since his arrival he has examined, in company with the committee on fire department, the fire alarm telegraph headquarters at the city hall, and viewed the workings of the fire and water departments and the principal apparatus houses. While in the house of engine 22, a house alarm was pulled in from box 81, which brought quickly to view engines 3, 13, 22 and 23, ladders 3, 12 and 13, chemical 2, and hose 5 and 7. The gentleman has been entertained in true Boston style—evening entertainments, drives through our unrivaled suburbs during the day, and visits to all the prominent points of interest have been made.

M. Garcien expresses himself well pleased with the system of the Boston fire department, though he considers that of New York to be conducted under a discipline more strict. The visitor much admired the comfortable quarters furnished to the firemen in the larger American cities. He has left Boston to visit Philadelphia.

"The alarm sounded," so a burglar found to the cost of his personal liberty Nov. 7th, as he entered a gentlemen's furnishing store on Court street, the patrolman for the Boston Electric Protective Association hastened to the scene and found the man caged and unconscious of the signals he had sent in. The alarm was connected with a bulkhead which the burglar lifted.

Chairman Whiting, of the police board, accompanied by police commissioner Osborne, superintendent Small, and Mr. Irving, chief-clerk of the police board, are on a trip to visit Philadelphia, Chicago, and other cities. The object of the tour is to inquire into the working of the police signal system in the cities mentioned, with a view of adopting the same or some other here.

A company has been formed to run tram-cars by electric motors between Lynn and Nahant. The Nahant people want more conveniences in this direction. The Boston and Lynn horse railroad company was the first petitioner for track locations, and therefore opposes the new company. It is thought that the Nahant people prefer the electric scheme.

It is reported that the International Bell Telephone Company (limited) has the money for another 2½ per cent. dividend in January. This company operates in Europe. In its financial statement of June 18, the company expressed confidence in its ability to pay 5 per cent. on its capital of $1,387,000 in 1885, and the above report is in accord with this expectation.

The protest against the increase of telephone rates has continued during the past month. The total loss to the company by removal of instruments will not be great, as it is probable that the increased rates will fully if not more than offset the loss in rentals from such removals.

A lively meeting was had in Worcester. About 100 gentlemen were present. William H. Earle presided, and J. P. Cheney was secretary. Mr. Earle read a committee report claiming that the cost of a telephone station, exclusive of the royalty paid the Bell company, should not exceed $25 yearly, and that the royalty of $14.60 was exorbitant. The managers of the local exchange claim that the average cost of maintaining the service in Worcester last year was over $45 a station. After speeches by G. L. D. Newton, Alderman Thayer, Alzirus Brown, C. G. Parker, J. C. French and others, in which complaints of poor service were as loud as those against advanced rates, the subscribers present voted unanimously to order their telephones out November 15, unless the old rates were restored and the company gives guarantees of better service. It was stated at the meeting that a paper to this effect has already been signed by more than one-third of the subscribers to the Worcester exchange.

More than a hundred telephones are used by the various departments of the city of Boston, some of them being on special wires. In consideration of this large number, and of the valuable privileges granted to the telephone company, the city fathers have thought that the company would allow some reduction from the regular rates paid by other subscribers. Such allowance has not been made; the city pays the regular price and receives no special privileges. Last year the city's telephone bills amounted to $12,881.58. The city cannot dispense with the telephone service, which is of special value in the police department, but Mayor O'Brien thinks the charges are excessive, and he has been in correspondence with the mayors of other cities in regard to the rates for telephones elsewhere. The charges in various places are shown by the following table:

	Rates per year. Subscribers.	Rates per year. Cities.		Free telephones granted cities.
Albany	$...		$ 60	..
Baltimore	100	Ordinary	67	..
		Fire department	30	..
		Water "	100	..
Boston	120		120	..
Brooklyn	100	Ordinary	90	..
		Leased instrument	20	..
Cincinnati	100		..	..
Chicago	125		10	25
Cleveland	72		20	20
Detroit	..	One-half usual rates.		..
Lawrence	75		36	..
Lowell	75	One-half usual rates.		..
New York	150		150	..
New Haven	60		..	..
Portland	75	One-half usual rates.		2
Providence	60	One-half usual rates.		3
St. Louis	100		100	..
Worcester	75	Instruments at special rates; connect free.		..

In Cincinnati, Cleveland, Detroit, Portland and Worcester the city has the right to use poles for department wires. In Chicago

Digitized by Google

the city maintains the leased lines and the telephone company maintains the free lines. In Lawrence it is agreed that the rates paid by the city shall not be raised. In Lowell the fire and lamp departments pay $25 a year. In St. Louis the telephone company pays two and a half per cent of its gross receipts to the city until 1890; after that the company is to pay five per cent. In New York, as in Boston, no privileges are granted, and no reduction from the regular price is made.

The committee on streets, Lawrence, Mass., held a meeting Nov. 12, to consider the petition of nearly 600 residents of South Lawrence to have the city government retain electric lights on the bridges and railroad crossings between Lawrence and South Lawrence. All present were unanimous for retaining the lights. After the hearing, the committee voted unanimously to recommend to the city government that the proposition of the Lawrence Electric Light Company to furnish lights for bridges, the Common and public streets, at the rate of $10 per month be accepted. About 20 electric lights are now in use.

The property of William A. Ingham, C. J. Glidden, Loren N. Downs, Alonzo A. Coburn and William H. Bent, the original telephone syndicate, has been attached for $150,000 each by General Butler and William H. Anderson, on behalf of the Erie Telephone Company, in a suit to recover $127,000, the amount of money paid for certain properties in the west, in which it is alleged the syndicate committed fraud against the company in that they sold it to the Erie company at an advance of $87,000 above what they paid for it while directors of said company. This is the outcome of a special meeting of stockholders held at Albany in September.

Henry K. Goodwin was arraigned before the Supreme Court at Salem, Nov. 6th, to plead to an indictment for murdering Albert H. Swan, at Lawrence, Aug. 27th. Mr. Swan, it will be remembered, was a prominent operator in Bell telephone stock and territory, and at the time of his death was largely interested in the Molecular Telephone Co. General B. F. Butler and Colonel J. P. Sweeney appeared as counsel for defense. Goodwin answered to the indictment, "I did it, and always said I did." General Butler entered a plea of "Not guilty." The trial was fixed for Dec. 28.

The telephone stocks have been somewhat weak, pending the discussions held before Secretary of the Interior, Lamar, during the last week in Washington. The American Bell stock has fluctuated from $1.72 to $1.75—dividend off. The Erie telephone stock, at the time of writing, is sold higher than that of the New England company; why it should is one of the enigmas of the stock market, as it has short contracts with the parent company which must be renewed to be perpetual ones, when of course the main company will receive a share of stock for the perpetual lease—while the New England company has long contracts and is "married to her lord.

The superintendent of the Boston division of the New England Telephone Company announces under date of Nov. 1: This company has completed direct copper wires from Boston to Worcester, Mass., and Portland, Me., points heretofore reached with difficulty by telephone. Other extra-territorial lines have been reconstructed with favorable results. While delays incident to telephonic communication with extra-territorial points are sometimes unavoidable, all possible facilities will be given to subscribers; and it is believed that the time consumed in securing a connection will compare favorably with other modes of communication.

BOSTON, Nov. 20th, 1885.

ELECTRICAL NEWS AND NOTES.

THE ELECTRICAL SUBWAY COMMISSION.

INVESTIGATIONS AT PHILADELPHIA, WASHINGTON AND CHICAGO.

On Friday, November 13, Commissioners Loew and Hess, with Mr. John Thomson, representing Commissioner Moss, started upon their tour of inspection of subterranean electrical work in the cities of Philadelphia and Washington. They were accompanied by several gentlemen interested in the subject, and the party arrived at Philadelphia early in the afternoon. They were met at the station by W. H. Johnstone, general manager of the American Sectional Electric Underground Co., and David Brooks, representing the Brooks Underground Cable Co. It was arranged that the Brooks system should be first visited, and as the preliminary examination was to consist primarily of a telephone test, Mr. Thomson, accompanied by Mr. Palmer, of the Brooks company, drove to Kensington, the remainder of the party going to the office of the company, 310 Chestnut street, these being the terminals of a line which is about 2½ miles long. The telephone tests proved perfectly satisfactory in every respect when the line was arranged in metallic circuit, but induction was apparent to a considerable extent when the wire was grounded. It is but fair to state that the inductive effects were far more apparent over the regular overhead telephone wires of Philadelphia than they were in the underground wires in either of the cities visited. No attempt was made either to verify connections, or to make elaborate tests of the circuits. After satisfying themselves that telephones were in actual use, as had previously been stated by Mr. Brooks, the Commissioners were escorted to the eastern terminus of the cable, in the basement at Third and Chestnut. At this point the wires are fanned out to a joint-board where the necessary connections may be made. All of the wires used are of small gauge, suitable only for telegraph or telephone purposes. No arrangements for local distribution were shown, although in New York city connecting boxes for the Brooks system are located every 45 feet. Indeed, as used in this city, it is in every way more complete than in Philadelphia, excepting, perhaps, in the length of a single circuit.

According to the state law, as interpreted by the Commissioners, it is essential that the system adopted should be in the nature of a conduit, and for this reason the American Sectional system was examined with considerable interest, it having been devised with a view to the accommodation of all classes of wires. The conduit and the man-holes are of cast-iron, although in special cases, where gas, water or sewer pipes are encountered, the man-holes are built of brick in order that they may be shaped properly, and when built up to the proper point are surmounted by the cast-iron top, with an ordinary cover of the same material. The construction is in sections, the man-holes being composed of iron rings several inches wide, placed one above another, to such height as may be necessary. At such points as may require a junction with a lateral, a ring is used having a "spigot," to which the conduit is connected. By this system of construction it is obvious that the man-hole may accommodate a conduit brought in from any direction or at any height. Those in Philadelphia vary in depth from say four to eight feet. The conduit is made in four sizes, designated as A, B, C and D. The outside shell is cast in sections about four feet long, in the form of a trough. These sections are joined longitudinally, the ends breaking joints. The edges are smeared with plumbers' putty after the lower section is laid down. The internal shelves and partitions being put in place the upper section is then placed upon it, and the whole firmly drawn together by a clamp secured by a pin The interior of the conduit is so arranged that the positive wires may run on shelves on one side, the negative wires on the other, while the telegraph and telephone wires are expected to occupy the centre compartment. The two upper compartments are appropriated to local distribution, and are accordingly provided with hand-holes located one in front of each building, covered with about two feet of earth. The trunk lines are drawn through the lower compartments. If, however, a wire is required for house service between the man-holes, it is there selected and led through one of the upper channels, where it is readily accessible when the cover of the hand-hole is raised. House connections are made by boring through from the cellar with an auger and inserting a sufficient length of ordinary gas pipe to reach the conduit. Several hand-holes were opened at different points, one house being selected at random by the Commissioners. The corresponding mark on the curb stone was found and the opening made in fifteen minutes. All were found in good condition. There are about 1¾ miles of conduit laid up Chestnut street from Third to Broad, with two branches. It has been down nearly two years. Considerable trouble was caused at one time by the accumulation of illuminating gas in the conduit, which, being ignited, caused explosions, throwing the man-hole covers into the air. One of these was particularly severe and tore up the street for a distance of three squares. Owing to the apprehensions of danger to life under the then existing conditions, it was decided to introduce a current of air by artificial means in order to drive out the gas. A blower has been arranged for this purpose, and air is now forced into the conduit from the lighting station at a pressure of about three pounds to the square inch. The blower is started about two hours before the lamps are lighted, and the result is perfectly satisfactory, although a complaint was raised last summer by people doing business on Third street in the vicinity of the end of the conduit, that the stench from the gas driven out was very obnoxious.

As there appeared to be no disposition on the part of the various electrical companies to utilize the conduit in Chestnut street, a company was organized under the title of the Underground Electric Light and Power Co., for the purpose of demonstrating that electric lighting could be successfully maintained through underground conduits. For twenty-one months they have continued a system of public lighting on Chestnut street, the only consideration for which has been the use of the dismantled gas posts upon which the lamps are placed. There are six arc light circuits in the conduit for which number four copper wire is used, insulated with pure Para rubber covered with braid and sheathed with lead, the outside diameter being half an inch. The office of the company is at 123 South 11th street, where the arc lighting plant is located. The power is supplied by a double 175 h. p. Cummer engine, run at 120 revolutions per minute. The Arnoux-Hochhausen dynamos have been used heretofore, but the Mather is now being introduced and is highly spoken of. After the lighting circuits were started up, the single telephone and telegraph wires through the conduit were informally tested, but although working satisfactorily, the system was so limited in its

Digitized by Google

extent that it did not really prove that the same results would attend the burying of a large number of telephone lines in close proximity to electric lighting wires.

On Saturday the Commissioners witnessed the drawing in of a section of electric light wire between Seventh and Eighth streets. The operation has not as yet become sufficiently familiar to the curious citizen and prevalent small boy to prevent their gathering in considerable crowds to witness the operation. The single wire was drawn in by one man, and was not so heavy as to show any detrimental effect from abrasion.

The Belmont pumping station, at Fairmount Park, was next visited by a portion of the party, the others going to the reservoir, these two points being connected by a subterranean telephone line using the Waring cable. The circuit is also connected with the telephone exchange system of Philadelphia, and by this means is considerably affected by induction. After cutting this off with a ground the underground line was found to be remarkably clear, as of course was to be expected, it being a two wire "anti-induction" cable forming a round circuit, which was grounded where the air line was cut off. Under the escort of chief Walker, the recently established telephone patrol service was inspected. Although not in the line of underground investigation, this branch of the police telegraph system was examined with considerable interest, as it appears to be a very important adjunct of the police department either in small or large cities. Every patrolman within the district which is now equipped is obliged to report by telephone, upon reaching the end of his beat. His voice is recognized and a record made of the time of his visit to each of the patrol boxes, which define the boundaries of his beat. In case a prisoner is captured, instead of taking him to the station he proceeds to the nearest patrol box and calls for the wagon, which starts at the tap of a bell, and like the fire apparatus, is always ready for immediate departure. As the horses take their places the harness is adjusted, the driver springs to his seat, and at the same motion throws open the doors, a sergeant and private jump into the wagon, and the prisoner, whether drunk, sober, crazy or ugly, is soon whirled up with style and despatch. Relieved of his charge, the patrolman at once resumes his duties, and his beat is at no time necessarily abandoned.

Chief Walker, in order to give his visitors an opportunity to learn his idea of an underground conduit, led them through the cellar of the new City Hall, a building which, although not yet completed, has absorbed about $11,000,000 in construction. The quarters of the police and fire telegraph are to be equal if not superior to anything of the kind in the world. The wires are to be brought in underground through an arched conduit of brick and cement, 5x6½ feet in dimensions, and 80 feet in length. A large water pipe is to be laid in the bottom, after which a brick floor will be placed over it, and the walls will be in perfect readiness to permit the stringing of overhead cables or wires "underground."

President Bentley, of the Local Telegraph and Bell Telephone companies, is making preparations to put down over a mile of the Wyckoff pump log conduit, of the same pattern as that used by the Western Union Telegraph Co. in Washington. Mr. Bentley considers the cable devised by David Brooks, Jr., as the most satisfactory for telephone work. The wires in it are supposed to be shielded from the influence of induction by the use of tinsel wire, with which groups of the insulated conductors are wrapped. The whole is sheathed in lead and filled with insulating material—not paraffine. Experience in Philadelphia has not been favorable to the extended use of this insulation.

The city authorities of Philadelphia reserve to themselves the supervision of the electrical lines, both aerial and subterranean, to the extent of specifying the height and size of the poles, the routes of lines, the height at which lamps shall be suspended, etc. Whether or not this may be the reason, it is certainly the fact that overhead wires are more carefully strung than in New York; the arc lighting wires through Chestnut street especially presenting a very neat appearance. In this instance iron poles have been used, which, however, are not quite strong enough for the service.

The city of Washington, which was next visited by the Commission, has been popularly supposed to offer some examples of what has been practically accomplished in the line of underground work. As an engineering problem the difficulties to be encountered are hardly more intricate than would be met on a Western prairie, there being apparently room enough for all companies who desire to undertake the burial of their wires.

Perhaps the best known underground system, and that which has given entire satisfaction to the government officers for two years past, is that of the Waring cable manufactured by the Standard Underground Cable Company of Pittsburg. The pattern adopted for this work is the six wire anti-induction cable, and it is employed in the making up of a combined telephone and telegraph system, by which the various government departments are placed in electrical connection with each other. The character of the buildings, the nature of the grounds, and the satisfaction of having wires which are entirely free from the annoyance of crosses, escapes, induction, and the various evils which beset our best managed lines, are the combined influences which in this particular instance make every officer and employé an earnest advocate of underground wires.

The first office visited on Monday morning was the War Department—the historic "Di," with which are associated the names of Eckert, Bates, Tinker, Chandler, and others, who were identified with this important post during the civil war. Various tests were made with the Capitol, a mile distant, over both Morse and telephone circuits, not for the purpose of attaining exact scientific data, but rather to prove that the system was practically perfect, as has been frequently asserted. Several other offices were visited, among them that at the Executive Mansion, where Mr. Montgomery uses the type writer for copying all messages received by sound. After completing the examination of the government lines the headquarters of the police and fire telegraph were visited.

Those who daily used the Waring cables in telegraphing and telephoning in various parts of the city were unanimous in their praise, and from personal knowledge of the unsatisfactory working of the lines which are generally used for this purpose, there can be no doubt that the improvement is most heartily appreciated.

The Baltimore and Ohio people had little to offer which was new to the Commission. Mr. Stewart stated that he had just finished testing a 600-foot length of the Averell system, in which bare copper wires are embedded in a prism of asphalt and silex. He had found the insulation more perfect than when it was first laid down, but no circuits had as yet been connected through it.

The Postal Telegraph and Cable Company have two wires running through Hurlbut's paper tube system. They had had considerable trouble arising from the breaking of wires in the man-holes, caused by the freezing of water in the winter. Manager Allen did not appear to be very enthusiastic over his wires.

The Western Union Telegraph Company, while it has no subterranean wires, has two "holes through the ground" three-quarters of a mile long. They are made of the cypress pump-logs, which are about six inches square, bored with three inch holes through the centre, and furnished in lengths of from six to eight feet. The wood is put down in its natural state, the ends of the lengths being so fitted that they may be firmly driven together. The completion of this line has been prevented by an injunction, as stated by the Washington correspondent of this journal. It is the only structure in the nature of a conduit which was seen in Washington.

The Chesapeake and Potomac Telephone Co. has placed underground about 12 miles of cable, the larger part of which are of the Patterson, and the remainder of the Phillips pattern. These are placed in 2½ miles of wooden conduit, filled in with asphaltum. Over $50,000 was expended for this work last year, while that remaining to be done will cost about $30,000. The official report of the company states that the cables work admirably, and that out of 1,150 wires leading from the exchange, one line of 700 and another of 450, one used a year and the other six months, not a single wire has become unserviceable from any cause. The distribution of telephone wires to subscribers in Washington is effected through the agency of distributing poles, which the authorities allow erected in the alleys, or in the centre of a block, up which the cables are led. It is rather a curious fact that while, according to the report of the company, "the public authorities have compelled us to transfer some of our lines from the overhead to an underground system," there had been erected in Washington during the previous nine months 295 poles, an increase of *ninety-five per cent*. These poles are generally very large, having a capacity of 50 or more single wires. Owing to lack of time no tests of telephone lines leading into the exchange were made, but so far as could be ascertained the gentlemen in charge appeared to be perfectly satisfied with the working of the system.

The Commissioners returned to New York on Monday, and started for Chicago on November 21.

The investigation of the subterranean systems of Chicago by the same gentlemen, was begun on Monday November 23. Some disappointment was expressed upon reaching the city, to find that apparently as large a proportion of the overhead wires were still in operation as had been found elsewhere, in spite of the fact that the date fixed by law for their final disappearance was as long ago as January 1st 1883. There are, however, no overhead wires for electric lighting purposes, neither are the streets lighted by electricity as yet, excepting to a limited extent by private enterprise.

The general business of supplying facilities for subterranean electrical communication is conducted by the Chicago Sectional Electrical Underground Conduit Co., which was originally organized for the purpose of laying down an iron conduit of the same character as that examined in Philadelphia. About two miles of this was laid in 1883, and a Patterson cable drawn through it where it still remains. The same company has since adopted the Dorsett conduit, which after two years service has been found so satisfactory, that about six miles have been put down during the past season. A very complete description of this conduit, was given in the ELECTRICIAN AND ELECTRICAL ENGINEER of November, in

Digitized by Google

the proceedings before the Commission on Electrical Subways.

As now used in Chicago it consists of cylindrical multitubular sections three feet in length, and ten inches in diameter containing seven ducts, each of which are 2¼ inches in diameter. The material composed of asphaltum silex, oxide of manganese and other ingredients, is molded under a continuous hammering process which gives it increased density and adds greatly to its strength, as well as other very desirable qualities for this purpose. The sections with a flange at one end are joined by a cement of the same material, and two lines are laid, making seven ducts for telegraph and telephone purposes, and the same number for electric light and power which are separated by about six inches of earth. In localities where it is necessary to provide for a great number of wires, larger pipes are used. The varieties of service already accommodated embrace the electric lighting, telegraph, telephone, ticker, district and time systems. The wires are usually encased in lead, either singly as in the case of arc lighting wires, or in cables, where conductors of but small size are required. The insulated arc wires used are ⅝ of an inch external diameter, and but four of them are placed in a duct, while for telephone purposes 100 may be accommodated. The Patterson, Waring, Day and Callender cables are used by different companies. The cables and wires could be examined only at the man-holes, which were opened at several points and found to be in apparently good condition. The man-holes, which are usually located at the intersections of streets, are made of the same material as the pipe, are bottle shaped, with a cast iron collar, and double cast iron covers, the exterior one being secured with a bolt and nut, the interior with a padlock. The pipe is joined to the man-hole wherever necessary, by chiseling a hole through its wall, inserting the end of the pipe and cementing the joint. The whole structure is thus made proof against the ingress of water, sewage or gas. An ingenious machine has been constructed for shoving a number four iron draw wire through the ducts from one man-hole to another. The wire is wound upon a reel, provided with the necessary gearing for turning by a crank. The end of the wire is led through a curved piece of gas pipe about six feet in length, and tipped with a traveler shaped like a soldering iron. The pipe is so curved as to lead the wire down from the reel into the end of the duct in the man-hole, which it enters horizontally. As the reel is then turned in the proper direction the wire is rapidly pushed through to the adjoining man-hole. At the corner of North Clark street and Chestnut place, the process of laying a lateral and joining it to a man-hole was witnessed. These laterals lead to the corners of the areas, under the sidewalks, from which the necessary wires are led for service on each block. Objections are being raised by property holders to the system of distribution heretofore practiced, and it will probably be modified to meet the requirements, as would necessarily be the case in other cities. To provide for the distribution of wires to every house, a hand-hole has been devised similar to the man-hole, but of much smaller dimensions, through which the cables are led. From this hand-hole smaller laterals are led, of similar construction to the main pipe, but encased in iron to give the requisite strength. From each of these hand-holes placed in the street, opposite the partition wall, four buildings will be supplied with any required service from the main conduit. The covers will be accessible from the street without disturbing the pavément, and like the man-hole covers are so secured as to prevent the ingress of moisture. A sample hand-hole was shown at the factory, which was next visited by the commission.

The process of manufacturing the pipe was watched with much interest. A sectional mould being placed on end under the plunger, the hot material is introduced in small quantities at about the consistency of mortar, and is immediately tamped by the plunger driven by steam, until thoroughly set, when another portion is added, and the process continued until the mold is full. The whole is partially cooled by a jet of water from a hose, and swung by a crane into a tank of water. The mold previously cooled is then removed from the tank, and opened, the end of the pipe trimmed, and the manufactured product is ready for shipment. At the suggestion of the commissioners a length of pipe was chipped and then broken in order to show its tenacity. Its evident strength was certainly surprising to several of those present who witnessed the test. The thorough manner in which the sections of pipe are manufactured impresses the observer with the idea that a conduit of this description must necessarily possess the qualification of durability for subterranean purposes. Its introduction in Chicago has to a certain extent carried it through its experimental stage, and the experience thus gained should lead to still better results in all future work.

At the head-quarters of the city electrical department the commissioners were shown the very complete equipment of the fire telegraph service in charge of Professor Barrett, who was very decided in his opinion that its efficiency had been increased, and its reliability assured by the introduction of subterranean wires. The first wires placed underground nine years ago are now in perfect order, being insulated with kerite and drawn through iron pipes coated with asphaltum. Prof. Barrett still uses the same class of wire through the Dorsett pipes, some of which are the property of the city, while others are part of the system owned by the conduit company. The telephone company use both aerial and subterranean cables. The tests made with telephones in Chicago, as well as the opinions given confirmed the previous investigations of the commissioners that the underground service is more perfect than usually obtains with overhead wires in cities.

The underground conduits of the Western Union and Baltimore and Ohio companies consist of cast iron pipes and brick man-holes. As soon as the necessary cables are received by the Western Union company, the wires leading from the corner of Washington and Lasalle to Taylor street will be connected underground, and the poles and wires of that company removed within a district covering about one square mile. The wires will not be placed in the ducts of the conduit company, as ample provision has been made for them by a special conduit under the franchise granted to the Mutual Union Telegraph Co.

The city of Chicago is farther advanced in subterranean work than any other place in America, not only so far as the actual operation of lines is concerned, but in preparations for the future. There appeared to be no question raised by practical men as to the successful working of underground wires, because the facts speak for themselves. For a more complete general history of the work, our readers are referred to the September, 1885 issue of the ELECTRICIAN AND ELECTRICAL ENGINEER, which may be relied upon as comprising all the necessary information regarding it, in a more comprehensive manner than can be attained by a brief personal examination of the ground. In fact the investigation of practical underground systems consists principally in the verification of information previously obtained from those who are familiar with their growth. Holes in the ground, or through the ground, present but little surface for satisfactory observation. To pursue the subject further, would require the assistance of a committee composed of rats and ferrets.

THE TELEPHONE HEARING BEFORE THE SECRETARY OF THE INTERIOR.

The hearing ordered by the Honorable Secretary of the Interior on the various applications for leave to bring suits in the name of the United States to cancel the Bell patent, No. 174,465, of March 7, 1876, was commenced at Washington on the 31st of October, before Hon. L. Q. C. Lamar, Secretary of the Interior; Hon. H. F. Muldrow and Hon. G. A. Jenks, assistant secretaries, and Hon. M. V. Montgomery, Commissioner of Patents. Hon. Casey Young, Hon. Bradley T. Johnson, R. J. Morgan and Mr. Humphreys appeared for the petitioners, and J. J. Storrow, Esq., for the respondents, the American Bell Telephone Company.

The Commissioner of Patents, in the temporary absence of the secretary, stated the object of the hearing, and said that three petitions had been filed, two by the Globe Telephone Company and one by the Washington Telephone Company.

In response to a question of the commissioner, Gen. Johnson said he had received notice from the department to appear and discuss two propositions, one as to the authority of the government to institute the proceedings prayed for, and the other as to whether the power being established, this is a case in which it ought to be exercised. He was ready to discuss both these questions. Mr. Storrow, in behalf of the respondents, stated that he proposed to inquire whether the Department of Justice has the power, under any circumstances, to bring such a bill; whether the circumstances are such that as a matter of law it has the power, or whether they are such, as a matter of law and under the decisions of the courts, as to prevent this from being done; and also whether, if such authority exists, it ought now to be exercised. He proposed to show that the most serious allegations of the bill, those of fraud and theft, were not only unsupported by evidence, but were absolutely disproved by the records of the department and the very papers presented by the petitioners. After considerable discussion between counsel, the Hon. Secretary stated that his understanding of the case was, that the counsel for the respondents deny the power of the government in any case to bring suit to vacate a patent regularly issued; they hold that the facts alleged, even if the power exists, do not make a case that comes within the constitutional competency of the government to bring the suit, and that even if they did, they still do not make a case which would justify the exercise of discretion to bring the suit, and finally that the facts themselves are proved by the records of the department and other evidence to be destitute of foundation. Mr. Young, in behalf of the National Improved Telephone Company and the Pan Electric Telephone Company, said that while agreeing in the main with Mr. Storrow, he controverted the proposition that the government had no power to institute a suit in any case. He (Mr. Young) apprehended that the question was likely to assume a magnitude not originally contemplated, and suggested that while he himself did not ask for a postponement, inasmuch as he was quite ready to argue the case as presented, yet if there was to be a postponement, he would ask that it be fixed at a day sufficiently distant to enable the leading counsel of the two companies represented by him to be present. He was confident that if it was controverted, he would be able to show by abundant authority coming down from the English law that it is a duty of the gov-

Digitized by Google

ernment, and that it has ample authority under our law and practice to institute the proceedings sought under the state of facts presented. Gen. Johnson said he was ready there and then to try the question of legal power and of fact; he wanted no authority from English courts. He could refer to decisions of the Supreme Court of the United States which would settle the question of law beyond all discussion. The Hon. Secretary said that he doubted whether the question of the legal issuance of the patent could come up before that tribunal. The secretary had no appellate power over the action of the patent office, and it appeared to him that the application to set aside the patent rather conceded its existence as a legal document. As a valid muniment of title, it had gone beyond his jurisdiction, and the only question now was whether he should advise the attorney-general to institute a suit to cancel it.

Mr. Humphreys said that the people he represented (the Globe company) were ready to go into business, but the respondents have such a power over the country that nobody is able to contest them except the government. He was prepared to show conclusively everything alleged in his petition.

Mr. Young suggested a postponement for a week to enable additional counsel from New Orleans to be present. Mr. Storrow thought that while the discussion would not take the range indicated by Mr. Young, it might go beyond a bare technical question of law.

The Hon. Secretary said that the department had notified the parties to appear and discuss certain propositions, which it might have gone on and investigated for itself; that counsel were before him as friends of the department, if they chose to consider it so, in reaching a conclusion, so that in postponing the hearing until another day it was merely consulting the convenience of its advisers. He therefore adjourned the hearing until Monday, November 9th, at 10 A. M.

On Monday, November 9th, pursuant to adjournment, the hearing was resumed. There was a large array of distinguished counsel present, in addition to those who appeared on the former occasion, among whom were Hon. George Gantt, of Memphis, and Hon. E. R. Beckwith, of New Orleans, and S. R. Beckwith, of New York, who represented divers of the petitioners; Chauncey Smith, of Boston, and E. N. Dickerson, of New York, representing the respondents, and numerous others. The room was crowded almost to suffocation with persons interested in one way and another in the proceedings.

Secretary Lamar, in opening the proceedings, stated that nine petitions in all had been filed in this case. Inasmuch as there seemed to be a concurrence of sentiment and wish by all the parties concerned in this controversy that the whole case should be taken up at once and considered as a whole, he preferred that there should be at present no discussion on the question of the power of the government to institute a suit to vacate a patent, and that the respective applicants, who are movers in this matter, should begin with their evidence and submit their cases.

THE VARIOUS PETITIONS SUBMITTED.

The first case called was that of the Globe Telephone Company, and Mr. Humphreys, the attorney for the company, read the petitions filed in its behalf, which set forth that the patent examiner who passed Bell's patent was under the impression that it related to a system of multiplex telegraphy; that he had not the least idea that it described a speaking telephone, otherwise he (the examiner) would have compelled Bell to have submitted the apparatus to a practical test. The device described by Bell in his specification was not and is not a speaking telephone, and this was admitted by Bell himself in a lecture subsequently delivered in London. The electric speaking telephone was not new. The oath of Bell as to his priority was not true. Reis, Meucci and Gray had made and used telephones before his application. Gray had filed a caveat setting forth the electrical art of transmission of articulate speech. The Commissioner of Patents had refused to declare an interference between Gray and Bell, although the records contained no positive proof of the priority in point of time of Bell's application. The petition further alleged that Antonio Meucci, of Staten Island, had conceived the invention of the speaking telephone in 1849, had made apparatus in 1855 and '57, and had published an account of it in 1864. In 1871 he filed a caveat, which he renewed in 1872 and 1873, but had been prevented by poverty, misfortune and disease from patenting or introducing his invention, but nevertheless had not lost his rights as a prior inventor, nor had he abandoned his invention. The pretended litigation under the Bell patent had been collusive. In the Spencer case Bell's priority had been admitted, but Professor Eaton, the maker of the apparatus complained of, was not permitted to testify. In the Dowd case the litigation had been compromised, and the Western Union Telegraph Company, controlling certain telephonic patents, had entered into a contract with the Bell company by which the Western Union company received twenty per cent. of the profits of the telephone company, and these great corporations had united to compel the people to pay tribute to them. Therefore, the Globe Telephone Company prayed the Department of Justice to begin suit to vacate the Bell patent.

Col. Gantt read the petition of the Washington Telephone Company, in which the allegations were substantially similar to the above.

Mr. Humphreys presented and read the petition of Sylvanus D. Cushman, of Ohio, another first, original and true inventor of the speaking telephone. Mr. Humphreys stated that there was a contract in existence made between Cushman and the Bell company by the terms of which Cushman agreed to remain quiet and not interfere with the Bell patents. That document was in the hands of the attorneys for the Bell company, and later on they would be called upon to produce it.

The petition of the North American Telephone Company, representing the McDonough inventions, was presented. It was signed by H. H. Eldred.

The Memphis petition, in behalf of the Pan Electric Telephone Company, was read by Col. Gantt. The allegations were in substance the same as those of the Globe company. It was lengthy and verbose, and was conspicuous for the extensive array of vituperative adjectives which it contained. It alleged, among other things, that Elisha Gray filed a caveat for a telephone on the the same day that Bell filed his application, and that, contrary to law, the contents of Gray's caveat were made known to Bell by an official of the patent office, and that within a few days Bell made an important amendment to his application, covering the matter described in Gray's caveat. Mr. Gantt stated that Solicitor-General Goode had acted upon that petition, after an examination of the authorities upon telephony and of the Reis and other instruments, by beginning the suit at Memphis.

Mr. Storrow stated that the Bell company did not propose to submit a formal answer to the petitions; it was sufficient to deny generally everything that had been set forth.

THE AFFIDAVITS OF THE GLOBE TELEPHONE COMPANY.

Mr. Humphreys then read a number of affidavits submitted in support of the petition of the Globe company, beginning with that of Zenas F. Wilber, an ex-examiner of the patent office, who was in charge of the electrical division at the time the Bell patent was passed. The affiant states that after an examination of Gray's caveat and Bell's application he suspended Bell's application and notified Gray to complete his caveat within three months. Those orders had been overruled by the Commissioner and revoked, and a patent issued to Bell. In all his experience in eleven years' practice affiant had not known of a similar ruling. Had the usual course been followed after the suspensory order, Bell could not have received a patent, and had Meucci's caveat been renewed in 1875 no patent could have issued to Bell. Affiant did not suspect irregularity at the time. He did not suppose that Bell's application was for a talking telephone, but for multiplex telegraphy, and is convinced that his device as described in his original application is inoperative as a speaking telephone.

Prof. A. K. Eaton, an electrical expert and inventor, of Brooklyn, in his affidavit, deposes that the Reis apparatus is capable of transmitting speech. He also described Meucci's invention, and stated that in his opinion Reis was the inventor of the telephone. L. S. Pratt, of the editorial staff of the New York *World*, in his affidavit, corroborates the statements of Mr. Eaton, and declares that Eaton to his knowledge in 1875 constructed an operative speaking telephone.

Prof. Amos E. Dolbear, of Tuft's College, Mass., makes an affidavit that he was told by a mutual friend of himself and Bell, in the fall of 1876, that he (Bell) had patented the magneto telephone two or three years before, and that it did not amount to anything. This statement had discouraged affiant, and he did not at the time carry out his intention of applying for a patent for his own invention of the magneto-telephone. Affiant's instrument had, through the Gold and Stock company, come under the control of the Western Union Telegraph Company, and affiant was not represented at the interference proceedings before the patent office because of the fact that the Bell company controlled his inventions. Attached to Prof. Dolbear's affidavit was a number of exhibits in the shape of letters from a number of college professors testifying to the merits and practicability of the Reis instrument.

Mr. S. R. Beckwith, general manager and counsel for the Globe company, read an affidavit of Antonio Meucci, describing his inventions, and a great number of exhibits in the form of telephones, alleged to be reproductions of actual working instruments made and used by him many years ago, were laid before the secretary to support his allegation. Meucci recounted his struggles against extreme poverty, which, he says, prevented him from taking out a patent for a telephone conceived by him in 1849 while in Havana, and for which he had made a caveat in 1871. A long transcription from his notes of experiments in telephony, ante-dating the Bell patent, was read, and a number of correlative affidavits were submitted, closing the case for the Globe and Washington companies, after which the case was adjourned for the day.

As Secretary Lamar was occupied in attending a cabinet meeting, no session was held on Tuesday.

The proceedings were resumed on Wednesday, Nov. 11, at 10 A. M., the same counsel as before being present on both sides. There were, perhaps, not quite so many patent attorneys and un-

Digitized by Google

retained lawyers present as on Monday, but scientific men, inventors, stockholders, speculators and the public generally, showed an unabated interest in the proceedings.

Prof. Bell was not present, but Prof. Gray, who was regarded as one of the most important persons in the dispute, was in attendance all day, and lawyers who are not engaged in the present proceeding, but have been and are still interested in other suits against the American Bell Telephone Company, were there, conspicuous among them being Mr. A. Q. Keasby, of Newark, N. J.

Col. Gantt, Col. Young, Mr. Humphreys and Mr. Beckwith renewed the assault upon the "telephone monopoly" with dozens of affidavits from university professors and high scientific authorities in Germany, telling of lectures delivered at Frankfort-on-the Main, and at other places in Germany as early as 1860, and continuously for years afterward, by Prof. Philipp Reis on his invention, which he called the telephone, for transmitting articulate speech. Not only did counsel submit affidavits of those who saw the telephone in operation and actually conversed over it, but numerous extracts from German newspapers, scientific periodicals and books printed twenty years ago were produced, containing reports of Reis's inventions and experiments, which it was contended showed that the art of transmitting articulate speech over a wire by electricity was a matter of public knowledge at that time. Prof. William J. Green, electrician at the Smithsonian Institution in Washington, testified that he made an exact copy from one of the original Reis telephones, received in the institution in 1874, and that it transmits articulate speech perfectly.

The following ingeniously ambiguous affidavit was put in from Thomas A. Edison:

I reside in New York. I am 38 years of age and am by occupation an inventor. I am the Thomas A. Edison, the patentee mentioned in the English patent of July 30, 1877, No. 20909, for a telephone. The inventions described and stated in that patent were made by me in 1875, the experiments continuing from that time right along, and culminating in the carbon telephone now universally employed. The transmitting telephones now used by the American Bell Telephone Company employ that invention. The dates of some of my patents are, as I verily believe, stamped upon their transmitters. I had no knowledge of Bell's inventions in speaking telephones when I made that invention. I had no knowledge of the Reis publications at that time.

A copy of a book entitled "Philipp Reis, the Inventor of the Telephone," written and compiled by Silvanus P. Thompson, professor of experimental physics in University College, at Bristol, England, was put in evidence, containing many communications from scientific men, contemporaries of Reis and witnesses of his work, which the author of the book collected and published about two years ago—all these documents and sworn affidavits of living men constituting, as Col. Gantt contended, a powerful body of contemporaneous testimony, which, unless it can be overthrown, puts the question of the invention of the telephone beyond controversy.

The petitioners put in another affidavit of Z. F. Wilber, the examiner in the patent office who examined Bell's application, to the effect that he was now of the opinion that the law was infringed by the patent office in giving Bell information which ought not to have been given to him about Prof. Gray's application for a caveat filed on the same day as Bell's application for a patent.

The petitioners reserved their heaviest gun for the last assault. Before resting their case they introduced an affidavit made by Prof. Elisha Gray, of Chicago, before G. A. Armes, a notary public for the District of Columbia, the 9th instant. The affidavit, which was read by Col. Young, contains matter that is likely to bring about an important controversy, and we have therefore thought best to reprint it in full. It is as follows:

AFFIDAVIT OF PROFESSOR ELISHA GRAY.

I. Having received from the government a number of patents which were supposed, among other things, to relate to telephony, I made a conveyance of the same to the Harmonic company in the year 1876. In consideration of that conveyance I received a stock interest in the said company.

II. This company conveyed to the American Speaking Telephone Company all its right, title and interest in said patents, so far as they related or might relate to speaking telephones. The Harmonic company received, in consideration of said conveyance, one-third of the stock of the American Speaking Telephone Company. My interest in this stock was owned jointly and equally by myself and Dr. White of Philadelphia.

III. The American Speaking Telephone Company, the Harmonic Telegraph Company, the Gold and Stock Telegraph Company, and the Western Union Telegraph Company, were the real defendants in the suit of the American Bell Telephone Company, commonly known as the Dowd case. Some time after the institution of this suit, a compromise was effected between the complainant and the defendants, by which the complainant company and the defendant companies jointly owned all the patent rights involved, the American Speaking Telephone Company receiving in said compromise twenty per cent. of the royalty received upon all the patents owned by the said companies. It was also to be interested in future patents that might be acquired by the combination, and was to contribute its proportion of the purchase-money expended in acquiring such new patents. From that time forward the said company was also to pay its part of any litigation that the combination might be involved in. Soon after the beginning of the Dowd suit, the subject of a compromise was suggested, and before finally consummated it was generally understood that a compromise would be effected; that the parties in interest could probably make more by a compromise and by owning the patent rights of the several companies as common property, than could be made otherwise, and that such a settlement especially was better than the hazards of the ultimate result of the litigation. Before said combination was effected, and after it was substantially understood that a settlement would be made, it is my belief now the litigation was not carried on energetically and in strict good faith with the view of an arms-length litigation and a final settlement by the court. This resulted from the fact that a determination by compromise was looked to by the several parties in interest.

IV. After this settlement, the property being owned by the complainant and the defendants in the proportion agreed upon, there was of course, as I suppose now, no such thing as litigation in good faith, but from that time everything was done for the common benefit of the complainant and the defendants, and such decree was entered in the case as they desired, the whole being conducted in such manner as to subserve the common interest.

V. I had no control over this case at any time. The corporation in which I was interested as a stockholder represented such interest as I had. After the terms of settlement were agreed upon, then the interest being common, the cause was carried on to a conclusion in a way to promote the common interest.

VI. I was the inventor of an electric speaking telephone. I described that invention in a caveat which I filed on the 14th day of February, 1876. I afterwards learned that on the same day Professor Bell filed an application for an improvement in multiple telegraphy. I learned, but not until after his patent on said application was issued, that in the said application he claimed to have discovered and invented an electric speaking telephone. Not long after my caveat was filed I received notice that an application had been filed that in some way conflicted with it, and that I must prepare an application on my caveat with a view of declaring an interference on account of said conflict. Soon after this I learned that the interference had been dissolved. I did not then know that the supposed conflict was between my caveat and the said application of said Bell. In March, 1876, a patent issued to said Bell upon his said application. I am informed and believe that a few days after the issuance of said patent said Bell made an instrument with which he transmitted articulate speech. Long afterwards I learned that the instrument with which he first transmitted articulate speech was a liquid transmitter, and substantially the same as that described in my caveat, but wholly unlike anything described in the said application and patent of said Bell. I believed, and remained under that belief for a long time, that said Bell actually invented the instrument with which he thus first transmitted articulate speech. I then believed that he and I were both aiming at the same end, and that each, without knowing what the other was doing, had discovered and invented a speaking telephone. At the Centennial Mr. Bell exhibited a telephone which transmitted articulate speech. I witnessed the exhibition. He did not use a liquid transmitter on this occasion but used an instrument very nearly resembling the receiver of my invention. I communicated this fact to my counsel and requested his opinion as to how my case stood in view of said fact. He informed me that practically my claim was defeated, that Bell's application was filed the same day as my caveat, and that Bell having made an instrument that successfully transmitted articulate speech, he occupied a better position and would undoubtedly succeed. I then did not for a moment suspect anything wrong, but supposed that in the eye of the law Bell had, as my counsel advised me, the advantage. Every oral statement made by me on the subject, and every letter written by me, which in any way indicated that I regarded said Bell as the original inventor of the telephone, with probable priority in the eye of the law over my discovery, were made and written under the belief then entertained as to perfectly fair dealing with regard to my caveat. Recently and long since the oral statements were made and the letters referred to were written, and long since I gave my deposition in the Dowd case and in the interference cases in the patent office, facts came to my knowledge that convinced me that I was wrong in assuming and believing that Professor Bell had fairly made his invention. But I now believe that he, on the contrary, had learned in some way of my caveat and of its contents; that he made use of that knowledge in constructing the instrument with which he first successfully transmitted articulate speech. I supposed my discovery remained a secret in the patent office, as it should have done, and was not known to Mr. Bell at the time he made his first successful transmission of speech. What I now state on the subject is made in view of this information which satisfies me that Mr. Bell, having obtained my secrets, claimed my discovery as his own, and by this means got the credit of my invention. Acting, however, at the time under the belief of his fairness in the matter, and advice of my counsel as to my rights, as before explained, I made such statement and gave said depositions.

VII. Being under this belief I did not take steps to file my application upon my caveat promptly, but the matter rested without any application until November, 1877. This long delay will be understood in view of what I have already stated. Some time prior, however, to the filing of said application, it was suggested by the American Speaking Telephone Company, under the idea that it was the owner of said caveat, that an application had better be filed any way for a patent upon the caveat, that some advantage or benefit might be derived from it. I accordingly filed my application. This was my act thus done and done by my counsel at the request of said company, but before any further steps were taken under said application, except to declare an interference between my application and the Bell patent, the compromise had been effected between the contestants in the Dowd case, and acting under the belief which I then entertained that by conveyance the American Speaking Telephone Company was the owner of said application and said caveat, and the rights therein mentioned, and believing that these rights had become the common property of the complainant and defendants in the Dowd case compromise, believing that whatever interest I had was only as a stockholder in the American Speaking Telephone Company, and that under that compromise I had no longer any financial interest in pressing the interference suit, nor had the American Speaking Telephone Company, as it was immaterial how that contest was terminated, provided it was done in such a way as to subserve what was believed to be the common interest of this combination. After the combination, and without any action on my part, the said interference suit growing out of my caveat and the application thereon was again set in motion and conducted to a result. I was examined as a witness in the interference suit, my deposition being taken in the city of Chicago. I had no counsel employed, however, and took no interest in it, and only gave my deposition when called upon by the combination referred to. These companies, as they believed, and so did I at the time, held and owned all the patents and all the claims in said interference case and the other interference cases that were carried along with these, and although there appeared to be opposing counsel and a struggle and a contest, and much proof was taken, deponent verily believes that there was really no struggle and no contest, and that it was intended to carry these interference cases on and bring out the final result in such a way as best to subserve the interests of the combination made up by these three corporations. By looking at the record of these cases, it appears that I had counsel; that I was a litigant actually contesting this matter, and asserting or attempting to assert the priority of my discovery over that of Prof. Bell's, and the other alleged discoverers and inventors that were made parties to the same controversy. Such was not the fact, however. I had no counsel, I was not a litigant; the whole apparent discovery was, as I now believe, collusive, and carried on with the appearance of an array of opposing counsel, that these counsel all understood each other, and were working for a common end agreed upon beforehand by the combination. It was supposed, as I have lately been informed, that these interference suits thus carried on and worked out would strengthen the claims of the corporations that were engaged in carrying them on in their interest. I was not consulted except to give my depositions, which I did when called upon, and did render them in the honest belief that Mr. Bell had the advantage which I have already mentioned as explained to me by counsel. The counsel named in the record as representing me in the said interference suit were paid, as I understand, by the said combination, consisting of the parties complainant and the parties interested in the Dowd case, in pursuance of their agreement and understanding all the litigation carried on for their joint benefit was to be paid for by the combination. Not only was this the case, but one of my counsel, so called, was at some time—the precise time I am unable to state—retained for the American Bell Telephone Company, and is now in its employment, as I learned some time since when speaking to that counsel with the view of a proposed employment which might conflict with the interests of said company. It is not a fact that the result in the Dowd case was reached by a trial

Digitized by Google

upon the merits and a decision according to the merits, but it was reached by the agreement and understanding of the parties in interest. Nor is it a fact, as I believe, that the interference suits were carried on upon their merits in a real *bona fide* controversy, but on the contrary I believe that said interference litigation, although seemingly hostile, was really friendly, and the result reached was not a decision upon the merits in a hostile controversy, but in a collusive controversy, in which the only parties interested were the parties in interest in the Dowd litigation.

VIII.—The stock which Dr. White and myself received for our interest in the sale to the American Speaking Telephone Co., for the patents embraced in that sale, all went to Dr. White, as by our contract he had a lien upon my half for debts which I owed him, and my half was absorbed in the payment of these debts. I subsequently bought stock, and by speculating in it made something.

IX.—In some correspondence that passed between Prof. Bell and myself in the year 1877, I accorded to him credit as an actual discoverer and inventor, which was done, however, under the belief that he was entitled to priority, and that without any knowledge of my caveat he really had been enabled to appear to be a discoverer and inventor, when such was not the fact, as I now verily and truly believe. I also wrote them under the belief and advice of my counsel that by reason of his claiming to have filed his application before my caveat, and of his practical demonstration with an electric speaking telephone, made according to my discovery, but which I then supposed was made according to his own independent discovery, that therefore, in the eye of the law, his claim would take rank over mine. About the same time that said correspondence took place I delivered a lecture in the city of Chicago, when I exhibited the instrument claimed by Prof. Bell as his invention. In order that the matter may be properly understood it must be borne in mind that the letter in which it is claimed that I gave Prof. Bell credit as an original inventor was written long before I knew that his first transmission of articulate speech was with a liquid transmitter like that described in my caveat, and that at the time of writing said letter and giving the lecture I only knew of the transmission of speech made at the Centennial with an instrument made like my receiver, which I had never used as a transmitter.

X.—The opening and concluding arguments of the counsel who nominally represented me in the interference case, but really representing the said combination, and in whose employment he then was in said interference suit, conceded the discovery of the broad art to Mr. Bell, claiming for me only a device or improvement on the art which Mr. Bell was conceded to have discovered. I did not know until long after that such was the case, but it plainly appears on an inspection of these arguments which I have lately made. These arguments, however, are in harmony with the intent of the combination and to carry out its purpose in these collusive and simulated contests.

XI.—The combination claimed my caveat and all the rights thereunder by virtue of my conveyance to the Harmonic Telegraph Company. I did not intend to convey it, but I labored under the belief that I had been overreached, or by mistake had conveyed more than was in contemplation when the trade was made. After being informed that I had been wronged in the patent office touching my caveat, either by design in disclosing my secrets or by remissness or accident, and that it was my discovery with which Prof. Bell first transmitted speech soon after my caveat was filed, as I am informed, and believing that he has learned my secret, I concluded that I would have the said conveyance examined by counsel, which I did, and was advised that my said conveyance did not cover the caveat, but only certain specific patents then granted, and which it was supposed by the purchasers related, among other things, to telephony, and which patents they believed, although not granted expressly in reference to that art, yet embraced the principles that might be controlling in contests touching it. I was misled by the assumption on the part of said company and its assignees that said contract covered said caveat, and I labored under this mistake until I had the contract examined as above stated.

After the conclusion of the reading of Prof. Gray's affidavit, Mr. Young read a letter from himself to the counsel of the Bell company, calling for the production of contracts alleged to have been made between the Bell company and Elisha Gray, the Gold and Stock and Western Union Telegraph companies, Messrs. Blake, Berliner and others. In his letter Mr. Young explained that he wished to establish by these contracts that the alleged telephone inventions of Bell were invalid; that the Dowd suit was inconclusive, and was only brought to obtain a judicial decree sustaining the patents; and that Bell and his associates entered into an unlawful combination to control all telephonic discoveries. In answer to Commissioner Montgomery, Mr. Young said that he expected the counsel for the Bell company to produce the papers on the following day. If they failed to do so, he would endeavor to introduce testimony showing the nature of the papers required.

THE RESPONDENTS PRESENT THEIR CASE.

Mr. Storrow, in presenting the case in behalf of the respondents, said that he had caused the bill of the Memphis petitioners to be reprinted in order to get at their allegations with technical accuracy. He said that the affidavits read for the most part were not affidavits produced here, or even copies of papers sworn to for this purpose, but were mere copies from the records in former suits, which resulted in decrees by the courts in favor of the respondents. Handing to the secretary copies of the moving papers in the Baltimore case against the Pan-Electric company, he called attention to certain letters written by Bell a year, more or less, before the patent issued, stating that he was then at work inventing the speaking telephone, and showing that that was his controlling thought. An affidavit from Mr. Watson, Bell's assistant, relates how the telephone was offered to and received by the public, and how it went into commercial use, and by long extracts from contemporary publications shows that Bell's telephone in 1876 was received as an absolute novelty, with the general consent of mankind that nothing of the sort had ever been known to the world before; that the first telephone line for any useful purpose in the world was equipped by Bell in Boston in the spring of 1877. Watson relates the rapidity with which the invention was introduced, until in six or eight years there were 300,000 instruments in use in this country alone, not to mention the rest of the civilized world. Mr. Bell exhibited at the centennial exhibition two forms of speaking telephones, one known as the liquid transmitter and the other as the magneto transmitter. Mr. Storrow then explained the construction of the telephone used at the centennial, which is familiar and need not be repeated, and showed how a correspondence between aerial waves caused by the utterance of a given word and the electric waves in the conductor is the prime essential for transmitting speech. Mr. Bell's apparatus produced and utilized just that correspondence; and was the first which had ever done so. That is exactly what is expressed by his invention in the fifth claim of his patent. Mr. Storrow then referred to the exhibition of the magneto transmitter and receiver at the centennial for the first time June 25, 1876. The exhibition was arranged primarily to enable Mr. Elisha Gray to show his harmonic multiple telegraph. There were present the Emperor of Brazil, the judges, of whom Professor Joseph Henry was chairman, Professor Barker, and about 75 persons altogether. After Mr. Gray had completed his exhibition of his harmonic telegraph, Mr. Bell asked permission to exhibit something which he had. He produced his speaking telephone and they talked through it. The Emperor of Brazil listened and repeated to the audience what he heard, and so also did Sir William Thomson. Elisha Gray was present; he listened at the instrument and repeated to the audience what he heard and they cheered, and he testified in his deposition in the Dowd case that it was the first time in his life that he ever even listened at a telephone receiver. The report of Professor Henry, chairman of the committee, declared that the apparatus was "the greatest marvel hitherto achieved by the electric telegraph," at least a prima facie assurance that in 1876 a speaking telephone was a marvel and a novelty.

The affidavit of W. C. Tompkins states summarily the litigation with reference to the Bell patent, and gives extracts from the opinions of the courts sustaining the patent upon every occasion. The affidavit of Mr. George Gifford, now deceased, counsel for the Western Union Telegraph Company in the Dowd case, stated what the settlement of that case was, and how it came to be made. Mr. Storrow said that the courts before whom this affidavit had been presented had said in effect that the opinion of Mr. Gifford that his clients could find no defense to the Bell patent, and that he was satisfied that Bell was the first inventor of the telephone, was very persuasive. Mr. Gifford's affidavit concludes as follows: "This settlement never would have been advised by me if I had not believed, upon the record or through the facts which I could ascertain, that the Bell patent was valid and that all microphones and carbon transmitters, as far as I knew or could ascertain, infringed it." Mr. Storrow said that it would appear elsewhere that before the negotiations for a settlement were commenced, the evidence in the Dowd case had been taken and printed.

Handing to the secretary a printed book containing the opinions of the courts and the patent office, Mr. Storrow referred to the opinion of commissioner Paine, the examiner of interferences and of the board of appeals, which commissioner Butterworth in his opinion sustained. He explained the points at issue in the different telephone interferences; the first one for example raised the question "who was the first inventor of the speaking telephone in the broadest sense;" the next, "who was the first inventor of one particular way of transmitting speech, to-wit: by means of a variable resistance transmitter," and so on as to the various forms and details of the invention. The final decision of the commissioner gave to Bell every issue in which he was involved.

In reply to a question from the commissioner of patents Mr. Storrow said that Gray was a party, and was decided against as to all his claims by the examiner of interferences. He did not appeal on the broad claims but only on the issues that concerned the broad construction of the receiver. Mr. Storrow then submitted the affidavits of Mr. Bell, and of Messrs. Pollok and Bailey, the solicitors who obtained his patents. These affidavits explicitly denied all fraud, contrivance or concealment, or any fact tending to show the same, and stated fairly and fully what the facts were. An important affidavit from ex-examiner Z. F. Wilber was then submitted. Mr. Storrow said that after making the affidavit which had been read by Mr. Humphreys, in which Wilber stated that when he passed upon the Bell application he had no sort of an idea or suspicion that it contained a speaking telephone, he had made another affidavit, the one now submitted. The most material statements in it are as follows:

As I have elsewhere testified, and as appears by the record in the case, on the 29th of February, 1876, an amendment was filed by the attorneys for Mr. Bell, which amendment was incorporated into the case. Such amendment was made to more clearly set out the difference existing between the invention in this case and an invention of Mr. Bell's, set out in a prior pending application filed by him early in 1875. The amendment did this. It was made for such purpose and extended to such object only. It was not based upon the Gray caveat, had no relation thereto, and in no way interfered with or limited any rights of the caveator, over and above the application as originally filed. As I have elsewhere testified, this amendment was not sworn to. It was admitted thus unsworn to, because, in my opinion, it contained no new matter.

He states that he has carefully examined a copy of the Gray caveat interference notice and other proceedings, and says:

These things indicate to me that I *did* know that the Bell application was for a speaking telephone, for otherwise I could not have used the terms I did in notifying the caveator, and in fact could not have determined that the application and the caveat interfered, or were in conflict.

Mr. Storrow next showed from Mr. Gray's deposition in the

Digitized by Google

Dowd record that he received the notice of interference, which he soon afterwards learned was with Bell's application, by a letter from his attorney, Mr. Baldwin, and also a copy of Bell's patent the same month of its issue; that at the centennial when he listened at Bell's telephone he heard the nearest approximation that he had ever heard to articulate speech, he repeated to the audience what he had heard, and they cheered; after listening to Bell's apparatus on June 25th, 1876, he then for the first time in the world undertook to make a speaking telephone, and was unsuccessful. He read also from the Dowd record a letter from Professor Gray to Professor Bell asking permission to explain and exhibit "*your* method of transmitting vocal sounds" in a lecture, mentioning that he himself had filed a description of a talking telegraph on the same day. In a lecture at New York he publicly stated that his (Gray's) telephone had been confounded with the speaking telephone invented by Professor A. Graham Bell, of Boston.

At this point proceedings were adjourned for the day and were resumed on Thursday, November 12, at 10 A. M.

Mr. Storrow continuing, put in the affidavit of Mr. Davidson, managing clerk of Messrs. Baldwin, Hopkins and Peyton, to show that the notices issued by the patent office in the prospective interference between Gray and Bell were in accordance with the usual practice of the office at that time.

Mr. Storrow then said he would read some evidence bearing directly upon the important question of alleged fraud. He read from the record of the Dowd case a letter of Professor Bell, dated March, 1875, giving an account of his interview with Professor Henry, and related how he had asked Professor Henry's advice about the apparatus which he had designed for the transmission of the human voice by telegraph, and the encouragement he had received from him, saying in conclusion that he believed it was feasible and that he had got the clue to the solution of the problem. Mr. Storrow said that in the Dowd case the precise question of the relations between Mr. Gray and Mr. Bell in the patent office had been raised, and was one of the chief foundations of the defense, in verification of which he read a long extract from the amended answer to the complaint. He then read from Bell's deposition in the Dowd case giving an account of his interview with the examiner in regard to the prospective interference; that the examiner said, "it is a caveat. I cannot show it to you," but that he (the examiner) took up Bell's application, then pending in the office as originally filed, pointed out a certain passage in Bell's own application, and said "it is something on that page that the caveat interferes with." Could there be a straighter statement that the common matter in interference was already in Mr. Bell's papers? He then read from testimony of Mr. Gray, and of his confidential assistant, Mr. Goodrich, in the same case. Mr. Gray testified that the invention described in his caveat was suggested to him by seeing a lover's telephone on the street; that his first definite notion communicated to any one was on the 11th of February, 1876. This was the first date tending to show any conception in his mind. No date of invention for him can by any legal possibility go back of that. He (Gray) gave a sketch to Goodrich and told him to have Mr. Baldwin's draughtsman put it in shape and he would file a caveat on it, which he did on February 14th. A letter written by Gray to Bell before the controversy began in 1877, shows that he already knew that his caveat was filed some hours later than Bell's application. Several letters which passed between Mr. Gray and his solicitor, William D. Baldwin, of Washington, were put in, the most important one being that dated March 3, 1876, from Baldwin to Gray's partner, Dr. S. S. White, of Philadelphia, which has been already given in Gray's affidavit, and for lack of space is not reprinted here. Gray took no steps to contest the application even after a copy of Bell's patent had been sent him. At the centennial Gray listened to Bell's instrument, and while the audience cheered, and such men as Professor Henry and Sir William Thomson were filled with admiration, Gray was disposed to sneer at the thing as a trick or a toy. He tried to make an instrument according to his caveat; it would not talk, and he sneered the more. November 1, 1876, when Bell had already become famous, Gray wrote Baldwin: "As to Bell's talking telephone it only creates interest in scientific circles, and as a scientific toy it is beautiful, but of no commercial value." By the next year he began to think that the "toy" might bring fame and fortune. He still knew that he had done nothing, but wanted to keep alive such ground of pretention as he had, and wrote to Mr. Baldwin that he would like to keep the caveat alive. Next arose the contest between the Bell company and the Western Union which had acquired all of Mr. Gray's rights, claims and pretensions; at least he thought he had sold them and they thought they had bought them, and he got his pay, but now hopes to pick a flaw in the deeds. In the midst of the Dowd suit, June 5 1879, Baldwin wrote to Gray that he gathered from Bell's preliminary statement that Bell "had no success until he adopted the devices shown in your caveat after the grant of his first patent." Even with this knowledge the Western Union party decided that it was impossible to beat the Bell patent, and therefore made the settlement described in Mr. Gifford's affidavit. Beside the adjustment of pecuniary interests between the corporations, there were questions what patents ought to issue under various conflicting applications, in which the respective inventors might well have a personal interest of pride and of pocket. Thereupon Baldwin wrote Gray November 3, 1879, "You have personal rights in this matter which in my opinion can only be properly settled by the adjudication of the patent office. * * * My notion is to speed the cause and simplify the issue by letting each party disclaim what it cannot contest successfully and confine himself to the points to which he is entitled." Thereupon the parties so agreed in their contract of November 10, 1879, adopting the *rights of the inventors* as the basis. No one was so much interested as the two contracting parties that in order to insure the validity of the patents, the first and true inventor should receive them in each case. Moreover the Bell patent was then four years old; if a new patent could be got for Gray it would extend the monopoly four years. The question was submitted to the patent office, and the interferences were prosecuted to their ultimate decision. While the expenses were expected to come out of the profits of the telephone yet the contest was similar to one where the cost of both sides, as in contesting the validity of a will or the distribution of a fund, comes out of an estate. In November 1881, the interferences were argued before the examiner. Mr. Baldwin made his case on the plan indicated. In his printed brief, he stated that the evidence in the Dowd case had satisfied the parties that the Bell patent was unassailable; that Gray was not the first inventor, and that therefore he retired from the contest on the broad claim to the transmission of speech, but he nevertheless insisted that Gray had invented the receiver a year before Bell. October 29, 1881 he sent Gray a copy of the brief containing this position in terms. Gray replied that the brief was a very able document which Baldwin should be proud of, and asked for additional copies which were sent. The decision of the examiner was against him. Baldwin advised him, August 3, 1883, to appeal on the receiver cases and let the rest go. Gray made no suggestion to the contrary, and Baldwin took that course sending copies of his argument to Gray December 18. The case was decided against him in the fall of 1884. November 6 he wrote to Gray that he should appeal to the commissioner, which he did and was again defeated. He and Gray corresponded about it both expressing great dissatisfaction, and Baldwin suggested an appeal to the courts to reverse the commissioner's decision. To all this Baldwin says Gray never made any objection, and never expressed any dissatisfaction, but quite the contrary.

Mr. Storrow then took up the matter of Antonio Meucci. Referring first to Mr. Lockwood's affidavit, the latter says that the defense that Meucci was the first inventor was set up in 1880 in the Spencer case, and in many subsequent cases, and the whole story was printed more than a year ago in the London *Electrical Review*. The caveat of Meucci, which must be conclusively deemed to contain the best he knew on the subject, does not, according to the affidavits of Messrs. Lockwood and Pope, describe an electric telephone at all, but merely a mechanical telephone with a notion that the effect can be increased by electrifying the operators—the silly notion of a crank. The affidavits in Meucci's behalf were an effort to show that in 1864 he had a perfect telephone, but was absolutely too poor to apply for a patent. His poverty is sworn to over and over again. One man, Dendi, swears that during all these years, he knew that the friends of Meucci would not help him procure a patent for the speaking telephone or any other invention, and would only give him the necessaries of life. May it please your Honors, Dendi and Meucci took out a patent as joint inventors two years ago. During the time when Meucci was so poor that he could not take out a patent for his speaking telephone, we find him *eighteen times* at the patent office, taking out over a dozen patents, to say nothing of other applications which have been rejected. Mr. Storrow submitted copies of more than a dozen patents taken out by Meucci, one of them, dated January 21, 1872, for "effervescent drinks;" one dated August 26, 1873, for "sauces for food;" one dated September 28, 1875, for a "lactometer:" and one dated October 10, 1876, for a "hygrometer." In fact, Meucci seems to be a prolific inventor. His first patent was issued to him in 1859 and the last one in 1883.

Mr. Storrow next referred to Prof. Eaton, who, he said, had made a curious affidavit, charging in substance that his own counsel in the Spencer case betrayed him. To meet that, his counsel, Mr. Betts and Mr. West, of New York, and his expert, Prof. Henry Morton, had been applied to, and their affidavits are now presented. Mr. Betts and Prof. Morton both say that they did their utmost to defend the case to the very best of their ability. Their affidavits were express and explicit to these two facts, that the defense in that case was that the Reis was a speaking telephone, that they did their best to get speech with a true apparatus—not a bogus one—but in vain; and they could get nothing from Eaton that would help them. They examined the Meucci case and his affidavits, and Mr. Betts concluded that there was nothing in the story fit to spread before a court. Two months ago Prof. Eaton's testimony was taken in the Overland case, when he said that in 1875 he tried to transmit speech with the Reis and could not do it. Mr. Storrow said that in fairness to Prof. Eaton it should be stated that he does not make a charge of unfaithfulness against his counsel; this was insinuated in an un-

Digitized by Google

sworn draft of an affidavit left here ten days ago, but he would not say it, for the charge is not found in the affidavit actually filed; it comes only from Meucci's counsel. Mr. Storrow then referred to the record of former cases, saying that more than nine-tenths of the evidence produced by the petitioners consists, not of affidavits, but of copies of affidavits taken last spring, and filed in the Pittsburg court as a defense to the motion on this patent against the Pennsylvania Telephone Company, and which were found by the court totally insufficient to defeat an injunction. To make a new case they can do no better than to copy an old one. He desired their honors to note that they were now called upon to hold an appeal from the decision of the circuit court of Pittsburg against this same apparatus, upon essentially the same evidence, printed copies of affidavits cut out of the printed book of the Pittsburg case, and submitted here with an affidavit of one of the parties that they are true copies. The instruments presented were also made for the Pittsburg case, and presented there.

Referring to the affidavit of Prof. Dolbear, and the appended letters, especially one from Prof. Dolbear's assistant, Mr. Buck, Mr. Storrow said that the instrument had been got in Germany, and put in evidence for the defense in the Dolbear suit in Boston. They swore that it would transmit speech, no trouble about it. They were asked to do it again in the presence of witnesses; they set up the apparatus and found that with the Reis transmitter and the Bell receiver they got speech; and with the modern carbon microphone and the Reis receiver they got speech, but that was not the Reis instrument at all. When they took *fac-similes* of the Reis instrument from Germany and coupled them up, Prof. Dolbear said he heard in the course of ten or fifteen minutes' trial *eight words*, it was found, when compared with what had been spoken at the other end, that *four* of these supposed words had never been spoken. Two days afterwards it was tried again with no better result. Judge Lowell, in deciding the case, said that Mr. Dolbear, in a book published in 1877, declared that it was an impossibility to transmit speech by the method or instrument of Reis. He now endeavors to assert a different view, but the experiments tried fôr the purpose in the presence of counsel were a signal failure. Referring to an article in the *Manufacturer and Builder* of 1869, written by Dr Van der Weyde, as showing the publicity of his invention, Mr. Storrow said that his express language in that article is that it is impossible to transmit speech by the instrument now set up as a speaking telephone. He would show, by comparing the Reis publications with the instruments produced by the petitioners, that the latter were not in any sense reproductions; that they have introduced features employed in the Blake transmitter for the very purpose of avoiding the action described by Reis. This matter was fully gone into at Pittsburg and the alleged reproductions condemned. The nature of the litigation at Pittsburg was then explained, the substance of the statement being that by agreement of counsel in that case it will go to a final hearing within a month, and be certified to the supreme court in order that it may be decided at the same time with another case now on the docket of that court, involving the validity of the Bell patent, and which, it is expected, will be decided at the present term.

Mr. Storrow then referred to the matter of contracts, and ridiculed the demand of the other side for the production by the Bell company of certain contracts to which it is not a party, and copies of most of which are not to be found in printed records. He said that Cushman's attorney had applied to his associate, Mr. Smith, two weeks ago, and proposed to take pay for suppressing the affidavits here presented. He wished also to state that so far as suppressing Cushman's knowledge was concerned, it could be proved that he published the whole story in the newspapers in 1881 or 1882, and again this year, that he told his story to the patent office in 1881, and that it is now on file there.

At this point the hearing was adjourned for the day and was resumed the next morning at 10 A. M.

Mr. Beckwith, counsel for the National Improved Telephone Co., stated that he was present during the Pittsburg trial only as a spectator, and had no pecuniary interest therein. But as a spectator his recollection differed materially from the statement made by Mr. Storrow yesterday. In that trial Mr. Storrow made a full exposition of his case, but before the defendants had an opportunity to reply the judge applied the judicial tourniquet, and said that on account of judicial courtesy and the courtesy which should be observed between judges of different circuits he would not consider the question of legality or construction of Bell's patent open for discussion on an application for a preliminary injunction, and that unless there was in the instrument used by the defendant something in construction that carried it out of similarity with the instruments proceeded against, then for the purpose of a preliminary injunction the matter was settled. As considerable importance was attached to that point by the other side he presented affidavits tending to establish the facts as he remembered them.

Mr. Young inquired of Mr. Storrow if the Bell company had not brought suit against the National Improved Telephone Co. in New Orleans and against the Globe company in New York since the commencement of this hearing. Mr. Storrow replied that the attorneys had been directed to bring the New Orleans suit long before the beginning of the present proceedings. In the case of the Globe company, it had been known for several years that such a company existed, but until a very short time past they had never offered to use instruments or take any step that would admit of the beginning of a suit by the Bell company. Within a few days, however, circulars issued by the Globe company had been discovered that furnished the necessary evidence for the institution of a suit. Mr. Young put in evidence affidavits of Prof. Waite and Prof. Paddock containing accounts of experiments made by them with the Reis and Bell telephones.

In answer to Mr. Young, Mr. Storrow declined to produce the contracts called for by the defense on Tuesday last, unless the secretary should signify a desire to have them produced. Upon an intimation from the secretary that he would like to see the papers Mr. Storrow agreed to produce them. Mr. Humphreys wished to have included in the records the patents of Hughes, Edison, and others, and various file wrappers and papers from the patent office records, and the evidence was duly admitted. He also read an affidavit by president Goodwin of the Globe company, testifying to Meucci's extreme poverty; that Meucci was oppressed by the American Bell Telephone Co., through the institution of a suit against him, and that the Bell company, through its attorney, had endeavored to purchase and acquire the claims of Meucci

Mr. Storrow—Who was that attorney?

Mr. Humphreys—We will point him out. You can name him.

Mr. Storrow—Who is he?

President Goodwin, of the Globe company, rose and pointed to a gentleman in the room. Mr. Storrow smiled, but did not offer to name the gentleman. Mr. Dickerson, however, stated that the gentleman was Mr. Tompkins.

Mr. Humphreys—I would like to ask whether he is the same Mr. Tompkins who managed the Eaton case for Spencer.

Mr. Dickerson—No, Sir. He has a different name and is a different person.

Mr. Storrow then replied briefly to the affidavits. He said that he had put in a sworn stenographic report of the Pittsburg trial. In answer to the allegation that the Bell company had attempted to buy Meucci's claims, he said that he could produce letters to show that the Bell company had been invited to go to Philadelphia to negotiate with the Globe company, and that they had sent down a representative, but the Meucci people had declined to show him anything, and he returned no wiser than he went.

Mr. Beckwith inquired if he would be permitted to put in a counter affidavit, sworn to by five gentlemen, to the effect that no such invitation had been extended by the Globe company; that the Bell representative had called upon Mr. Goodwin and associates and spoken of millions of money, and that the gentlemen representing the Globe company had drawn their watches and given the Bell representative 20 minutes to leave.

In answer to an inquiry by the secretary, Mr. Gantt said that if it was deemed desirable the petitioners would cause tests to be made of the workings of the various models submitted in evidence. If the other side assailed their testimony as to the workings of the models he would like to put in expert testimony in answer. The secretary expressed a preference for affidavits rather than oral expert testimony, which he said always had the effect of stampeding him.

Mr. Storrow expressed a wish to put in an affidavit by an expert. Touching this line of procedure the secretary said that the case would resolve itself into a question of expert testimony, and no doubt both sides could produce evidence to sustain their respective cases.

The counsel for the Bell company expressed a desire to examine and test the models submitted by the other side, and a long discussion took place between the opposing counsel as to the custody of the models. The secretary rather impatiently desired the gentlemen to come to an agreement; if they could not do that he would require the models to be examined in his presence. He explained that he was much pressed by official matters; another important case would come up for argument on Monday, and the case should be settled by that time. He believed that three hours ought to suffice for the presentation of each side—three for the petitioners as a unit, and three for the Bell company. The counsel expressed much discontent at this ruling. Mr. Young said that the case had assumed an importance far greater than he had contemplated when it began. Mr. Storrow said that the counsel had consulted together and regarded it as utterly impossible to make arguments in three hours. There were other issues here beyond the mere question of priority of invention. Charges of corrupt practice and fraud had been made and they require some attention. Finally the secretary decided to allow the Bell representatives two hours to prepare expert affidavits. The other side would be allowed a sufficient time to reply and the arguments must begin to-morrow. He begged the petitioners to condense their arguments into as short a time as was consistent with a proper presentation of their case.

The expert, Mr. F. L. Pope, of New York, finally examined the machines, and his affidavit was filed subsequently, in which

Digitized by Google

he states that the machines in evidence are the original Reis machines, with the addition of certain improvements which have been patented and are used to form the Blake transmitter.

When the hearing was resumed Mr. Bakewell, who was of counsel for the defense in the Pittsburg case, made a statement touching the proceedings in that case. He said the court had declined to go into the question of the validity of the Bell patent. Mr. Bakewell had offered to prove that the Reis instrument would transmit speech, and the court said if that could be shown he would refuse the injunction, but, on second thought, said that that point would make no difference, and the question of practicability of the Reis instruments was not discussed. The instruments were not explained to the court or looked at, except in a casual way.

Mr. Dickerson pointed out that Mr. Bakewell's statement placed the Pittsburg court in a very disagreeable light. He appealed to Mr. Bakewell to recall the facts, and try and remember whether Judge McKennan had not said that if Mr. Storrow would acknowledge that the Reis telephone would transmit speech then he would deny the injunction, and that Mr. Storrow had declined to make any such admission. Mr. Bakewell admitted that some such statement had been made, but said it referred to another occasion, and he persisted in his first statement.

The hearing was then adjourned, and was resumed on the following day at 10 A. M.

Mr. Storrow, for the respondent said, that he desired to submit a modern Blake transmitter as a sample, a correct reproduction of the Reis-Legat transmitter which has been in the patent office for several years, filed by Prof. Morton (an opposing witness in the Spencer case),and the patent of Blake. He also desired to submit additional affidavits. He then read a strong affidavit from Mr. Baldwin, who has been Professor Gray's counsel for years, in which he traversed most of the statements contained in the affidavit of Professor Gray in the present proceeding, and declared that Gray had never before intimated any dissatisfaction regarding the manner in which his interests had been looked after by his counsel. The correspondence between Gray and Baldwin, was admitted by the secretary after he had asked Professor Gray, who was present, if he objected, to which the latter responded, that he did not, provided he was allowed an opportunity for explanation. The letters were then read, and went to show that Gray then admitted the priority of Bell's invention. Further affidavits were submitted by Mr. Storrow in regard to the Meucci patents and his ability to pay patent office fees.

Secretary Lamar consented to give the counsel on each side five hours for argument. Before the case was opened he said that he desired to receive as early in the argument as practicable some information on two or three points. One was as to what constitutes an invention to such an extent that it will preclude the granting of a patent for the same thing to another person; the second was a question respecting the present condition of the telephonic art, and the third a question as to what constitutes good cause for the cancelation of a patent which has been regularly issued by the government to an inventor.

THE ARGUMENTS OF COUNSEL.

The argument was commenced by Mr. D. Humphreys, of Cincinnati, counsel for the Globe Telephone Company.

Referring to Zenas F. Wilber, formerly examiner in the patent office, who has at various times made affidavits both for and against Bell, Mr. Humphreys said that whatever might be alleged against his habits and character he was the man to whom Bell owed his patent and all the wealth that flowed from it, and Bell's action in spurning Wilber from his door, as he had done a few days since, was without parallel in the history of man's ingratitude. The legality or illegality of Bell's method of obtaining from patent office officials the knowledge of Gray's invention, which enabled him a few days afterward to file an amended application embodying Gray's invention, had never been tested in a law court. If it should by any possibility be decided against the mass of evidence adduced that Professor Reis's instrument was not a perfect speaking instrument, the testimony of Professor Eaton showed, at all events, that whether or not any improvements had been added to make it speak, the Reis instrument, with or without improvements, was employed in Brooklyn in 1875 by the Professor and Mr. Pratt, of the *New York World*, in conveying speech from one to the other.

Bell's method of making inventions and obtaining patents, continued the counsel, was pretty well illustrated by the case of Professor Dolbear. In September, 1876, the professor had invented a telephone to work on the magneto plan. He talked with Mr. Richards, Bell's friend, about it, and was informed that Bell had invented and patented the same thing two years before. Dolbear did not then think of proceeding for a patent, but in January, 1877, following, Bell taking advantage of what Mr. Richards had learned from Dolbear, applied for and obtained his first patent for a magneto telephone.

Mr. Humphreys charged boldly that in the interference case before the patent office every one of the persons there represented was purchased by the Bell company; every one of the counsel, including Mr. Baldwin, a highly respectable gentleman, counsel for Professor Gray, he said, was paid by the Bell company; and every sentence of that voluminous record was paid for by the same company. In conclusion, Mr. Humphreys appealed for an order to institute the suit prayed for; an order to go to the very bottom of all claims, and mete out exact justice to all.

Mr. Casey Young, for the Pan Electric company, continued the argument, cited other cases in which the government had taken up the fight in the public interest against monopolies without title, and claimed that even if no more than a reasonable doubt as to the validity of a patent were presented it would be the duty of the government to take up the question and have a test made that would be final. The legal mind of the country, he said, was not satisfied with the rulings of the courts upon precedents that had been obtained by the sham litigation of friendly parties working for a common end. He referred to some of the statements published respecting the Memphis petition, in procuring which he declared, the Pan Electric company had taken no part whatever. The government he said, upon the petition of private citizens has the power to bring a suit to annul a patent in any proper case, and the Bell patent is invalid because it is too broad in terms, undertaking to cover the operation of a power of nature, because it possessed no utility, was issued irregularly and fraudulently,and was anticipated by prior inventions. It would require hours for him "to elaborate the discussion as justice to himself and the importance of the questions demanded."

After the noon recess Dr. Beckwith made a speech in behalf of the petition of Antonio Meucci, of Staten Island.

At the afternoon session of the court, when Mr. Storrow rose to open the argument for Bell, Professor Bell was seated directly behind his counsel with several members of his family, and the room was crowded and jammed with eager spectators more than at any other time since the beginning of the contest. Mr. Storrow, in discussing what the law regarded as an invention and sufficient to anticipate another claim, said that it was not sufficient that a man should have conceived the idea of a telephone and intended to produce it; nor that he should have published a description of an invention in which, with the light of a subsequent invention can be recognized a description of a telephone. The description should be such that a person without any invention on his own part could construct the instrument referred to and obtain from it the desired results without making any improvements or additions not contained in the description; it was not sufficient even to have produced an instrument that would sometimes produce a result and sometimes not. The question to be asked is, who gave to the world the telephone? In answer to this question, Mr. Storrow pointed to the centennial report, in which Prof. Joseph Henry, after having had Reis's instrument in his possession at the Smithsonian institute two years, declared that Bell's invention of a speaking telephone was the greatest marvel of the age.

Mr. Storrow then read a prospectus issued by the Washington Telephone Company, one of the contestants, last year, in which, discussing the marvelously rapid development and consequently great commercial value of the telephone, it is said that it was first exhibited at the Centennial Exposition in 1876, and that the first line for practical use was constructed in Boston in 1877.

The power of the government to proceed against a patent since issued, said Mr. Storrow, does not exist in this country. It never was adopted from the English common law, because the subject is covered by statute, and, therefore, the common law is excluded, and because the express terms of some of the statutes on the subject are against it. To revoke a land patent, counsel said, was quite a different thing, for in doing so the government acted simply as a landlord, and as any other landlord would. If Bell's patent was obtained by fraud, that is no reason for revoking the patent. When a man commits a crime we are not to proceed against him in equity and confiscate his property as a punishment instead of sending him to state's prison.

The history of this movement, said Mr. Storrow, is, that in 1883 a syndicate of gentlemen purchased from one Mr. J. H. Rogers some patents for changes of form in telephone instruments, which in themselves were of no commercial value. The Bell company could have them enjoined from using the telephone, but there was one thing they might do. If they could avoid or stave off litigation and injunctions by any means for a time, they could in the meantime send out telephones and make money, or if they could even make people believe that they had this power to stave off litigation they could sell their stock; so the syndicate metamorphosed into a corporation with a paper capital of five million dollars, and in May, 1884, the syndicate became the Pan Electric Telephone Co., and resolved to issue five millions of stock against the Rogers patents. The Washington and Baltimore is a branch of the Pan Electric. About the same time the National Improved Telephone Co., sprung into existence for the same purpose, and went into business with similar capital. That company too, gave birth to several branches in various parts of the country. Suits have been brought against them, several of which are still pending, and it is to prevent decisions being given in suits already brought that this movement has been started.

To the charge made by the petitioners that a telephone made

Digitized by Google

according to Bell's specification would not talk, Mr. Storrow thought it was unnecessary to make any reply further than by referring to the affidavit of Prof. Nipher, one of the petitioners' own witnesses, stating that he had tried a Bell telephone made in exact accord with the specification and it did talk.

For lack of space we are obliged to omit the greater part of Mr. Storrow's masterly argument, as it is impossible to condense it, without doing it great injustice. We may be able to give it more fully hereafter.

The argument occupied the whole of an extra evening session. On Monday morning Nov. 17, at the opening of the session, Mr. Humphreys presented an affidavit sworn to by W. W. Goodwin, president of the Globe company, setting forth that in 1883 the American Bell Telephone Co., through its agents, did make overtures for the purchase of Meucci's claim to the invention of the telephone.

Accompanying the affidavits were letters and telegrams from the Bell company to the Globe company, arranging for an interview to discuss the proposed purchase. As an outcome of this correspondence Geo. M. Roberts, an attorney, and another gentleman, representing the Bell company, called upon a Globe official at Philadelphia, and one million dollars was mentioned as a sum to be considered in the negotiation. But the negotiation fell through.

Prof. Elisha Gray presented another affidavit and read it to the court himself. He said that in 1876, when his caveat was filed in the patent office, simultaneously with the filing of Bell's application for a patent, it was by advice of his counsel, Mr. Baldwin, that he refrained from a contest with Bell. His own caveat contained a full description of a perfect telephone, whereas he declared on his authority as an expert that an instrument made according to Bell's patent specification is incapable of transmitting speech, and the ordinary scientific knowledge of that time would not enable a man to construct a speaking telephone from Bell's description.

Mr. J. R. Beckwith made a very lengthy argument against Bell's patent, and estimated that Reis's publications of twenty years ago described a speaking telephone much more accurately and minutely than Bell's specification of 1876.

Mr. E. N. Dickerson replied for Bell, and, after taking up one after another the principal points in dispute, he closed with a fervid peroration, in which he drew a striking contrast between the honors which a grateful world had showered upon its greatest benefactor, and the jealousy of the ignoble, the cupidity of the avaricious, who, in less than ten years, had sprung up to rob the inventor of his honor in order to steal his property.

Col. Gantt, of Memphis, had just begun to make the walls shake with the force of his argument for the Pan Electric Co., when an adjournment was ordered to 8 o'clock.

When Col. Gantt at the evening session continued his address, the wisdom of Secretary Lamar in having arranged an evening session instead of hearing the colonel in the afternoon, when the building was full of clerks with work to do, was apparent. It would have been impossible for anyone to work in any part of the building while the colonel was speaking. It was no use closing all the doors. The learned counsel's oratory broke down all barriers and rang through the corridors to the most distant parts of the building, and even startled the passers-by on the street outside. He talked so loudly that he had not covered half of the subject or touched upon half the points at issue, when at 9:45 Secretary Lamar informed him that he had exhausted his allotted time. The points which he elaborated were, that on March 8, 1876, Mr. Baldwin, who, though nominally counsel for Gray, was really having his bread buttered by the "rhinoceros monopoly," had a consultation with Bell and induced Gray, who was not a man of the world, to relinquish his claim, which no honest counsel would have done even if Gray's claim had been as questionable, as it was beyond doubt good and genuine; that it was not in his application filed 14th February, 1876, but in an amendment filed two weeks later that Bell mentioned undulatory electrical currents, which he had stolen from Gray's caveat by favoritism in the patent office; that that amendment embodied what Bell claimed as the essence of the invention, the undulatory continuous current with variable resistance at the point of contact, instead of broken currents described in his original papers; and that that amendment, which was claimed to be the essence of the invention and the soul of the patent, was foisted in and not sworn to.

The first day on which Bell produced an instrument to transmit articulate speech was on May 10, 1876, which he did by adopting the liquid transmitter described in Gray's caveat, but never even hinted at in his own specification. When Bell completed his invention, if he had intended it to be a telephone, or a means of transmitting speech, he would have called it so; but he called it multiple telegraphy. Bell's experts he charged with fraud and with attempting to impose upon the court by presenting as reproductions of Reis's instrument what was quite different. An affidavit by Mr. Van Benthuysen was handed in in contradiction of the affidavit of Frank L. Pope. This was to the effect that the instruments presented on the part of the petitioners were exact copies of Reis's instrument, and were perfect speaking telephones. The Bell company, Col. Gantt said, in the Spencer case, obtained Judge Lowell's decision against the claims of Reis by preventing Prof. Eaton from swearing, for he would have sworn that Reis was the inventor of the telephone which he himself had improved and made to transmit and deliver speech in Brooklyn at least one year before Bell applied for a patent. To say that the Reis instrument was an infringement on the Bell was for a nine-year-old boy to say to his father, "Daddy, you infringe me."

After announcing that briefs may be filed by all who participated in the argument within ten days, Secretary Lamar declared the hearing dismissed.

THE PAN ELECTRIC SKELETON.

The following sketch of the organization of the now famous Pan Electric Telephone Co., is given by Mr. A. B. Talcott, electrician of the House of Representatives. The former electrician of the House was a young man of the name of Rogers, a son of J. K. Rogers, who made himself such a reputation in his card to the New York *Tribune*, wherein he related with such detail how he had distributed the stock of his company in Washington. J. K. Rogers is a very eccentric old gentleman. He has all his life been on the lookout for a fortune through chimerical schemes. His son was the electrician of the House. This son was called a genius by his friends. Mr. Talcott says that he knew very little of practical electricity. It was this son that invented the telephone upon which the Pan Electric company was formed. It is such an infringement of existing telephones that it has never been able to be put up in a single state in the Union. J. K. Rogers is a cousin of Casey Young Atkins, the Indian Commissioner, and of Senator Harris, all of Tennessee. He got these three cousins to go in with him to form a telephone company. This telephone company's capital stock was the genius of young Rogers. The original incorporators of this company paid in $125 cash, no more, and then began to issue stock. Young Rogers sold out his interest to some local people here for $80,000. This fact proves that young Rogers was the genius of the family. He is the only member of the company who has realized any large sum out of the company.

The whole enterprise was based upon nothing except the names of the men who went into it. The parent company has since authorized branch companies in various states in the Union. This is the way these branch companies were organized. The parent company would authorize the formation of a branch with a capital of one or two millions of dollars and would reserve to itself a certain proportion of the branch company's stock. All those who went into the branch company were required to sign a guarantee that they would not sell the stock except at par. The holders of the stock of the parent company were free from any such obligation. Since the formation of the original company, branches have been formed in New Jersey, Illinois, Indiana, Ohio and New York. Garland originally had given to him only 500,000 of this stock, but the increase upon his original stock from the reserves pledged by the branch companies to the parent company, has increased his pile of paper to a nominal holding of a million and a half. This stock must be very lightly valued by the holders of the original issue, for I understand that one of them a few days ago paid $1,000 of it for a week's board. The whole enterprise has the look of a grotesquely transparent scheme. There has never been anything done in the way of actual work beyond the mere printing of stock since the original company was formed. It is understood that the movement upon the part of the Pan Electric people against the Bell Telephone Co., was merely done to put off some of their extravagantly over-issued stock upon the public. Mr. Talcott says that the parent company and its branches have issued between seven and eight millions of stock. That fact alone should create a presumption against the honesty of the Pan Electric company, which owes its entire standing to the fact of its having connected with it the names of a number of officials who have put no money into the enterprise and who have large blocks of stock to sell.

EFFORTS TO INTERPRET THE NEW YORK UNDERGROUND LAW.

The following letter has been sent by Mayor Grace to Mr. Lacombe, counsel to the corporation, regarding the Electrical Subway Commission:

November 14, 1885.

Mr. E. Henry Lacombe, Counsel to the Corporation:

SIR.—I am instructed by the Mayor to ask your opinion on the following question:

Chapter 534 of the Laws of 1884 requires that every corporation, association, etc., owning or controlling telegraph, telephone, electric or other wires * * * shall before the first day of November, 1885, have the same removed from the surface of all streets or avenues in certain cities of this state.

Chapter 499 of the Laws of 1885, which supplement the act referred to, and which was passed on the 13th of June, 1885, authorizes and directs the appointment of commissioners in the cities referred to, who are charged with the duty of enforcing the provisions of the previous act.

Does the wide discretion vested in the commissioners by section four of the latter act, of deciding when and under what circumstances companies may re-

Digitized by Google

tain the wires overhead; and does the fact that by section six, the term of office of the commissioners is made to expire on the first day of November, 1887, or sooner, upon the performance of their functions, indicate that the intention of the Legislature was to repeal, by implication, the provisions of the prior act, which directed, absolutely, that the wires be placed underground by the first day of November? Respectfully,

WILLIAM L. TURNER, *Secretary.*

To which the corporation counsel replies as follows:

OFFICE OF THE COUNSEL TO THE CORPORATION,
New York, Nov. 18, 1885.

Hon. William R. Grace, Mayor, etc.

SIR:—I am in receipt of a communication from your office refering to chapter 534, of the laws of 1884, and chapter 490, of the laws of 1885, touching the placing of electric conductors underground, and asking whether in my opinion it was the intention of the Legislature to repeal, by implication, the provisions of the earlier of these two acts, which directed absolutely that the wires be placed underground by the first day of November.

By chapter 534, of the laws of 1884, it was provided that every corporation, association, or person owning or controlling telegraph, telephonic, electric or other wires and cables (including telegraph poles and other appurtenances thereto) should, before the 1st day of November, 1885, have the same removed from the surface of all streets or avenues in every such city. In case of the failure of the owner of the property above enumerated to comply with the provisions of the act within the time specified the "local governments of said cities" were directed to remove, without delay, all such wires, cables, etc., wherever found above ground within the limits of their cities. This act has never been repealed, and, except for such qualification of it as is to be found in chapter 499, of the laws of 1885, it is still in force. By the last cited act it is expressly provided (section 2) that the act of 1884 "is [thereby] amended and made to conform in all respects to the provisions of [the later] act." This later act requires the board of commissioners created thereunder to cause the wires and cables to be removed from the surface and put underground wherever practicable. No express language has extended the time within which the requirements of the earlier act are to be conformed to, and it is, in my opinion, very doubtful whether the provisions of the later act, regulating the course of procedure to be followed by the commissioners in selecting a general plan of underground subways, are so inconsistent with the earlier act as to justify the conclusion that it was the intention of the Legislature to modify it in that regard. This statute will undoubtedly have to be construed by the courts, and as the act of 1885 expressly relieves the city authorities of the responsibility of enforcing the provisions of the act of 1884, a further discussion of the question by the law department would seem to be unnecessary.

I am, sir, yours very respectfully,

E. HENRY LACOMBE,
Counsel to the Corporation.

ELECTRIC LIGHTING IN NEW ENGLAND.

Our traveling correspondent sends the following statistics of electric lighting in Fall River, Mass., and Providence, R. I.:

The Fall River Electric Light Company, using the Thomson-Houston system, has two Armington-Sims engines, 120 h. p., four dynamos, with a capacity of 130 arc lamps. There are in actual use 93 lamps, 25 of which are for public lighting, also a mill plant of 32 lamps.

The Edison Electric Illuminating Company, at Fall River, operates a central station with capacity for 3,400 lamps, and has wired for 2,000, including stores, hotels, theatres, churches and dwellings. Underground conductors are laid in three miles of streets. There are also nine isolated mill plants in operation, aggregating 4,000 incandescent lamps. The system has been in operation two years, and its competition has reduced the price of gas from $2.50 to $2.00 per thousand.

The Rhode Island Electric Lighting Company has a central station at 270 Dyer street, Providence, and uses the Weston system, both arc and incandescent. The power is furnished by two George H. Corliss engines of 200 h. p., each coupled to the same shaft, the belting shafts being connected by internal spur gearing; one Harris-Corliss engine of 80 h. p.; total capacity, 300 arc lamps of 2,000 c. p., or 2,100 incandescent c. p. There are now in use 90 arc lamps on four circuits, 676 incandescent lamps on four circuits, and 96 "mogul" lamps, 125 c. p., each on three circuits, all supplied from arc light dynamos. There are 18 dynamos of 20 arc lamp capacity, each of uniform size, that may be switched into any of the circuits as required. The lights are furnished to private subscribers only. The prices for arc and mogul lamps are 35 cents per night to 7 o'clock, 50 cents to 12 o'clock, and 75 cents for all night; incandescent lamps of 16 c. p., 8 cents each for 12 hours. There are in circuit 17½ miles of No. 4 wire. This plant is in very fine order.

The Narragansett Electric Lighting Company, using the Thomson-Houston arc and the Sawyer-Man incandescent systems, has its station at 52 Aborn street, Providence. Its power is furnished by seven Armington-Sims engines, two of 50 h. p., two of 60 and one of 90, a total of 410 h. p. It has four dynamos, each of 45 arc lamp capacity (1,200 c. p. each), two of 45, 2,000 c. p., seven of 25 and one of 30, a total capacity of 475 arc or 3,800 incandescent lamps. There are now in use 256 arc lamps, of which 75 are for city use, and 480 incandescent lamps, run from arc lamp circuits. The prices to the city are 33 cents per night; to private consumers, 50 cents to 12 o'clock and 75 cents all night. Eight incandescent lamps are furnished at the price of one full arc. The half arcs are furnished at 40 cents per night, or three for $1, up to midnight. They have unfilled orders for 50 more city lamps and 56 incandescents. The plant has been greatly enlarged and entirely refitted within two months, and has been in operation two years.

A NEW TELEGRAPH COMPANY IN MINNESOTA.

Col. W. I. King, of St. Paul, representing the North American Telegraph Company, says:

"The importance of Chicago, Duluth, Minneapolis and St. Paul as grain centres, and the experiences of the people of this city with present facilities, teach the necessity for a new telegraph enterprise in this section. We propose to start and complete as soon as possible telegraph lines from Duluth to Chicago, via Minneapolis and St. Paul. We have had offers from opposition lines which insure our system having the fullest facilities for home and foreign business. Our intention is to build and equip a system with the latest improvements, so that it will be specially adapted to extend the fullest accommodation to commerce. We intend to build it for cash, without any construction company or syndicate, but solely on the basis of stock which has been paid for at the rate of one hundred cents on the dollar. We intend to issue stock to the amount of $200,000, of which $75,000 will be held in the east and will remain under escrow for five years, precluding the possibility of any speculative combinations. Of the remainder we consider that $50,000 should be placed each in Minneapolis and St. Paul, and $25,000 at Duluth. We are offered all the money we want, but we are anxious to interest Duluth particularly, because it does a large amount of telegraph business, and we wish further that they be represented on the Board of Directors. We offer cheaper and more efficient service at rates that will be considerably less than at present."

REPORT OF THE BALTIMORE AND OHIO TELEGRAPH CO.

The indebtedness of the Baltimore and Ohio Telegraph Co. from April 1, 1877, to date, connected with the acquisition and extension of the commercial system, amounts to $3,872,693. This sum does not, of course, include the value of the telegraph lines on the Baltimore and Ohio railroad and branches, and is almost exclusive of the value of the district companies in the cities of New York, Philadelphia, Baltimore, Cincinnati, St. Louis and other points. The Baltimore and Ohio Railroad Co. has received the bonds and stock of the Baltimore and Ohio Telegraph Co. for its advances, and arrangements have also been made for the further extension of its commercial telegraph system. The Baltimore and Ohio Telegraph Co. is thus securely established on an independent and permanent basis. It has made a desirable contract with the Baltimore and Ohio railroad company, for the use of the wires on its system not needed for railroad purposes, and including that system it owns and controls 7,535 miles of poles and 54,972 miles of wire, covering all the leading cities. The policy has been to reach centres of large population, and thus, in the cities of 5,000 or over, it has, through 114 offices, reached an aggregate population of eight millions. The whole number of the company's offices is 1,148. These are at points at which it is believed over 75 per cent. of the entire telegraph business of the country is transacted. The steady and constantly increasing growth of the business of the Baltimore and Ohio Telegraph Co., through its first-class service and the low tariffs established, indicates the appreciation by the public of its value as a competitor to the Western Union Telegraph Co., which has at all times evinced its determined hostility and antagonism. As all the leading cities have now been connected by a complete and perfect system, the Telegraph company will be enabled to effect material reductions in its operating expenses, and the board feel confidence in expressing the belief that the enterprise, which they have thus so successfully fostered and developed, will, aside from public considerations and its business value to this company, prove a most remunerative investment.

TELEGRAPHERS' MUTUAL BENEFIT ASSOCIATION.

The annual meeting of the Telegraphers' Mutual Benefit Association was held in the Western Union Building, Nov. 19. Officers as follows were elected: A. R. Brewer, president; William H. Young, vice-president; Charles P. Bruch, secretary; E. T. Mackay, treasurer, and the executive committee as given were J. Merrihew, Joseph Uhrig, J. L. Edwards, C. W. Hammond and W. B. Gill. Receipts for the year were $76,105.43, and disbursements $66,872.13, leaving a balance on hand of $9,233.30.

ELECTRIC LIGHT AND POWER.

The Central Edison Light Company has been incorporated at Covington, Ky., by Henry Worthington, Archie Steward and H. H. Hoffman, to furnish heat, light and power by electricity; capital stock, $100,000.

The Electric Light and Power Company has been incorporated at Fort Worth, Texas, to establish electric light works, with a capital stock of $25,000.

Digitized by Google

The Steam Pump Company, Holyoke, has placed electric lights in its foundry department. The entire works are now lighted by electricity.

William Stanley, Jr., has leased the old Day rubber factory at Great Barrington, Mass., and is fitting it up as a laboratory to be used in the development of his inventions in the interest of the Union Switch and Signal Company of Pittsburg.

A company to be known as the Worcester Electric Power Company has been organized at Worcester, Mass. Mr. S. E. Hartban is general superintendent of the company. They purpose to introduce into Worcester the electric transmission of power for the operation of machinery for manufacturing purposes, and also for the operation of street cars.

MANUFACTURING AND TRADE NOTES.

The Washburn & Moen Company, Worcester, has recently enlarged its property by the purchase of 30,000 feet of land adjoining the south side of its works. The directors have voted to adopt the weekly payment system after January 1. They employ about 3,000 hands.

The Narragansett Machine Company received the second award for collective exhibition of foot-power machinery. They have a new screw cutlery lathe that is a favorite with electricians.

Jones, Denton & Co., contractors on the new aqueduct for New York, report that they recently ran a Westinghouse engine and a Ball dynamo thirty-six days without a stop, in lighting their tunnel work.

The Westinghouse Machine Co. have within the last thirty days shipped for electric lighting alone the following Westinghouse engines: Brush Electric Light Co., of Buffalo, three of 60 h. p. each, making the fifteenth order from that company; Toledo Electric Light Co., 65 h. p.; Cleveland Electric Light Co., a fifth order for 60 h. p.; Oshkosh Gas Co., for electric lighting, 50 h. p.; W. D. St. Clair, Chicago, one 50 and one 35 h. p.; George D. Sheibly, Fostoria, Ohio, 35 h. p.; The Pittsburgh Club, 35 h. p., with a complete incandescent plant, besides about twenty smaller engines to private parties.

PERSONAL MENTION.

Senor Don Saturnino Yslas, an electrician well known in America, has just been made director general of national telegraphs of the Republic of Mexico.

Mr. W. E. Huntington has been appointed general superintendent of District Telegraph Service of the Baltimore and Ohio Company, with headquarters in New York city.

THE TELEGRAPH.

The plant of the Postal Telegraph Company, including all its fixtures and all the wires underground and overhead within the District of Columbia, was sold at auction November 5 by United States Marshal McMichael, to satisfy a deed of trust. The only bidder was Mr. Hillyer, acting for Mr. S. C. Elliott, the plaintiff in the suit, who bought the property for $4,000. The judgment was for $10,000. It is said the underground wires alone cost the company $20,000.

The Arkansas Telegraph Company began building from Malvern to Little Rock on November 14, along the Iron Mountain road, when a construction train carrying fifty men arrived and tore down all the poles and wires, and drove the telegraph men from their work. On Nov. 16 R. E. Douglass, president of the Arkansas Telegraph Company, set his men to work building from Little Rock to Malvern, when the fifty men again arrived and destroyed the work as fast as it was done. Mr. Douglass was told that he positively could not erect his poles along the right of way of the Iron Mountain railway, and that 400 men were ready to prevent him doing so. He withdrew his force to prepare to call upon the authorities to protect him. The people will demand that the militia be called out for his protection.

SUBTERRANEAN LINES.

The Dorsett Underground Service Company has been incorporated, the object being to lay electric conduits in Milwaukee. The capital stock is $500,000, and the incorporators are Thomas Shea, A. W. Hall and Paul Bechtner.

SUBMARINE CABLES.

The cable connecting Nantucket with Martha's Vineyard was successfully landed at noon November 19.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER *by* Pope & Edgecomb, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From October 20th, to November 10th, 1885 (inclusive).

Alarms and Signals:—*Signaling Apparatus*, I. H. Farnham, 328,578, Oct. 20. *Gong*, J. P. Tirrell, 328,982, Oct. 27. *Central Office Apparatus for Fire Alarm Telegraphs*, L. H. McCullough, 329,186. *Non-Interfering Fire Alarm System*, same, 329,187. *Testing Apparatus for Fire and Police Telegraph*, same, 329,188. *Non-Interfering Fire and Police System*, same, 329,189. *Indicator for Letter Boxes*, E. E. Weaver, 329,245; Leo Ehrlich, 329,294. *Automatic Fire Alarm Telegraph*, M. Morris and J. C. Wilson, 329,468, Nov. 3. *Signaling Apparatus for Machinery*, M. W. Grovesteen, 329,830. *Thermometric Alarm*, John Barry, 329,698. *Call Box*, Frank B. Wood, 329,871. *Alarm for Locomotives*, W. Vogel, 330,074, Nov. 10.

Clocks:—*Speed Clock for Machinery*, W. H. Lord, 328,592, Oct. 20. *Clock*, F. R. Field, 328,769. *Time Detector*, T. Ahearn, 329,874, Nov. 10.

Conductors, Insulators, Supports and Systems:—*System of Electric Lighting*, T. A. Edison, 328,573, 328,574, 328,575, Oct. 20. *Conduit*, G. B. Pennock, 328,712; H. L. Caples and W. W. Lewis, 329,887, Nov. 10; T. D. Williams, 330,277. *Insulator*, L. O. Smith, 328,728; W. N. Fawcett and G. F. Huntley, 328,929, Oct. 27. *Street Curb and Gutter*, Geo. D. Sutton, 329,342, 329,343, 329,-344. *System of Distribution*, H. M. Byllesby, 329,621, Nov. 3. *Conductor*, A. C. Tichenor, 330,071, Nov. 10. *Means for Supporting Wires*, J. W. Tringham, 330,173.

Dynamo Machines and Motors:—*Floating Current Motor*, William Main, 328,496, 328,497, 328,593, Oct. 20. *Commutator for Dynamo*, C. E. Piper, 328,-859; T. A. Edison, 328,572. *Dynamo*, C. M. Ball, 329,118, Oct. 27; E. P. Clark, 330,095, Nov. 10. *Regulator for*, W. M. Schlesinger, 329,681, Nov. 3; C. E. Scribner, 330,053. Nov. 10.

Galvanic Batteries:—*Liquid for*, A. F. W. Partz, 328,607, Oct. 20. *Battery*, T. L. Kauffer, 328,687, Oct. 20; 328,948, Oct. 27. *Earth Battery*, G. F. Dieckmann, 329,724, Nov. 3.

Ignition:—*Gas Lighting Device*, D. Rosseau, 328,976, Oct. 27. *Gas Lighting Burner*, same, 328,977. *Testing and Firing Apparatus for Submarine Mines*, J. P. Gibbins, 330,226, Nov. 10.

Lamps and Appurtenances:—*Incandescent Lamp Switch*, C. R. Arnold, 328,831, 328,832, Oct. 20. *Arc Lamp*, A. G. Holcombe, 329,166, Oct. 27; H. Lemp, 329,461, Nov. 3; G. C. Pyle, 329,948, Nov. 10; C. E. Scribner, 330,053, 330,055; O. Romanze, 330,351. *Support for Lamps*, C. L. Travis, 329,510. *Holder for Incandescent Lamps*, C. H. Benton, 329,618; W. Stanley, Jr., 330,-269, Nov. 10. *Process of Obtaining Carbon for Incandescents*, S. Nicholson and H. A. Bowen, 329,670, Nov. 3. *Regulator for Lights*, P. Lange, 330,2[illegible] Nov. 10.

Metallurgy:—*Apparatus for Separating Gold from Ores*, W. J. Tanner, 328,-532, Oct. 20.

Miscellaneous:—*Joint for Wire, Cables, etc.*, C. G. McLeod, 328,502, Oct 20. *Governor for Water Wheels*, E. H. Amet, 328,556. *Perforator*, J. E. Munson, 328,600. *Switch*, S. S. Leonard, 328,695; H. Lemp, 329,460, Nov. 3. *Belt*, P. Wenigmann, 328,829, Oct. 20. *Filtering Apparatus*, G. H. Moore, 329,064, Oct. 27. *Cable Conveyance*, C. J. Van Depoele, 329,104, Oct. 27. *Governor for Steam Engines*, P. W. Willans, 329,112. *Wire Clamp and Coupling*, E. M. Hamilton, 329,162. *Mechanism for Operating Safe Bolt Work*, F. Sedgwick, 329,222, 329,223. *Medical Battery*, T. H. Hicks, 329,310. *Circuit Controlle.*, W. A. Leggo, 329,398, 329,399. *Manufacturing Thermostats*, M. Martin, 329,-469, Nov. 3. *Thermostatic Electric Controlling Device*, same, 329,470. *Burial Casket*, C. Sieber and F. H. Borntraeger, 329,495. *Compound Magnet*, S. H. Parkes, 329,708. *Induction Coil*, T. J. Perrien, 329,772. *Electric Magnet Armature*, J. Steiner, 329,782. *Circuit Breaker*, C. L. Bruns, 329,808. *Medical Apparatus*, A. Metzger, 329,929, Nov. 10. *Machine for Covering Wire*, J. McCahey, 330,035. *Spool Carrier for Winding Machines*, same, 330,036. *Automatic Circuit Closer*, P. C. McCambridge, 330,037. *Cable Armoring Machine*, W. R. Patterson, 330,047. *Method of Testing Cables*, same, 330,048. *Splice for Underground Cables*, same, 330,049. *Testing Apparatus for Lightning Arresters*, C. E. Scribner, 330,054. *Laryngoscope*, C W. Meyer, 330,139. *Carbon Electrode for Electrolytical Purposes*, H. Leipmann, 330,247.

Protectors:—*Electrical Apparatus Protector*, C. F. Elden, 329,152, October 27. *Protecting Structures from Lightning*. 329,853, Nov. 3.

Railways and Appliances:—*Electric Railway System*, F. J. Sprague, 328,-821, Oct. 20. *Signal*, H. C. Nicholson, 329,478, Nov. 3.

Telegraphs:—*Printing Telegraph*, C. N. Judson, 328,491, Oct. 20; W. J. McCausland, 328,500; S. B. Van Nortwick, 329,515, Nov. 3. *Apparatus for Maintaining Communication with Moving Vehicles*, L. J. Phelps, 329,076, 329,-077, Oct. 27. *Automatic Harmonic Recorder*, E. Gray, 329,386. *Multiple Local Circuit for Telegraphs*, F. L. Pope, 329,410. *Multiple Local Circuit for Electric Telegraphy*, same, 329,411. *Multiple Local Circuit for Electric Telegraphs*, same, 329 412. *Means for Adjusting Submarine Duplex*, A. Muirhead, 329,477, Nov. 3. *Siphon Recorder*, W. Dickenson, 326,723. *Means for Preventing False Signals on Reversals in Quadruplex*, J. W. Larish, 329,749. *Transmitter for Printing Telegraphs*, 330,2[illegible]8, 330,239, Nov. 10. *Telegraph Instrument*, G. W. Stewart, 330,271. *Automatic Perforating Telegraph*, J. E. Munson, 330,344.

Telephone Systems and Apparatus:—*Switch-board*, C. C. Sonne, 328,618, Oct. 20. *Telephonic Appliance*, J. F. McLaughlin, 328,702. *Transmitter*, same, 328,703. S. E. Beedy, 329,001, Oct, 27; F. D. P. Marstow, 329,827. *Telephone*, T. A. Edison, 329,030; J. H. Robertson, 329,084, 329,085; W. A. West, 329,983, Nov. 10. *Telephone Receiver*, J. H. Robertson, 329,083. Oct. 27. *Telephone Call Register*, A. S. Hibbard, 329,646, Nov. 3. *Sound Concentrator for Telephones*, J. Godfrey, 329,732. *Telephone Cabinet*, F. G. Johnson, 329,909, Nov. 10. *Combined Telegraphic and Telephonic Circuit*, A. M. and T. R. Rosebrugh, 329,956. *Receiver for Telephonic Telegraphs*, W. A. West, 329,982. *Telephonic Telegraph*, same, 329,984. *Battery Circuit for Exchanges*, C. E. Scribner, 330,056. *Exchange Signal*, same, 330,057. *Operators' Apparatus for Exchanges*, same, 330,058. *Multiple Switchboard Testing Apparatus*, same, 330,059. *Operators' Testing Apparatus for Multiple Switchboards*, same, 330,060. *Multiple Switchboard*, same, 330,061, 330,062; J. A. Seely, 330,067. *Operators' Apparatus for Switchboards*, C. E. Scribner, 330,-063. *Gravity Telephone Switch*, same, 330,064. *Exchange Switching Apparatus*, same, 330,065. *Toll Line Apparatus for Exchanges*, same, 330,066.
